Initially submitted May 13, 2014; accepted for publication January 16, 2015.

We examined whether changes in different forms of social participation were associated with changes in depressive symptoms in older Europeans. We used lagged individual fixed-effects models based on data from 9,068 persons aged ≥50 years in wave 1 (2004/2005), wave 2 (2006/2007), and wave 4 (2010/2011) of the Survey of Health, Ageing and Retirement in Europe (SHARE). After we controlled for a wide set of confounders, increased participation in religious organizations predicted a decline in depressive symptoms (EURO-D Scale; possible range, 0–12) 4 years later (β = −0.190 units, 95% confidence interval: -0.365, −0.016), while participation in political/community organizations was associated with an increase in depressive symptoms (β = 0.222 units, 95% confidence interval: 0.018, 0.428). There were no significant differences between European regions in these associations. Our findings suggest that social participation is associated with depressive symptoms, but the direction and strength of the association depend on the type of social activity. Participation in religious organizations may offer mental health benefits beyond those offered by other forms of social participation.

The recent Global Burden of Disease Study ranked major depressive disorders as a leading cause of disability (1, 2). In a study comparing 10 countries in Northern, Southern, and Western Europe, Castro-Costa et al. (3) reported that the prevalence of clinically significant depressive symptoms in older adults ranged from 18% in Denmark to 37% in Spain. Despite the high burden of depression in old age, there is limited understanding of its potential causes and of interventions that may help in preventing depression among older persons.

Lower social participation and less social interaction in old age are each associated with higher levels of depressive symptoms (4–15). Social interaction provides people with a sense of belonging and social identity, together with opportunities for participation in activities and projects (16). With some exceptions (17), several studies have found that active participation in religious or church activities, clubs, and political groups and volunteering are associated with better mental health and reduced levels of depressive symptoms (6, 8, 11, 13–15).

However, the causal impact of social participation on depression has not been well established. Associations may reflect confounding by unmeasured characteristics or reverse causality from depression to social participation. One source of confounding comes from permanent personal characteristics that differ between individuals and that may be associated with both depressive symptoms and social participation, such as personality traits, socioeconomic status, childhood conditions, or intellectual ability (18). For example, persons with certain psychological or personality traits may be more likely to engage in social participation and may also exhibit lower levels of depression, which could result in a spurious association between social participation and depression.

Fixed-effects models have been advocated as a useful approach for controlling for the impact of these permanent characteristics (19–22). Fixed-effects estimators, sometimes called “within-person” estimators, control for unobserved individual heterogeneity that may be correlated with the explanatory...
variable. They exploit the longitudinal nature of the data by assessing the association between changes in the explanatory variable and changes in the outcome variable within individuals, thus controlling for permanent characteristics that vary across individuals. This is in contrast to the more commonly applied random-effects or “between-person” estimators, which combine variation between individuals as well as within individuals for estimation. While confounding by unmeasured time-varying characteristics is also a potential concern in fixed-effects models, they can provide additional insights into the potential causal association between social participation and depression by controlling for individual heterogeneity.

Earlier studies linking social participation to depressive symptoms focused primarily on single populations or countries (5, 6, 13, 23–25). Levels of both depressive symptoms and social participation vary considerably across countries, possibly due to cross-national variations in the availability of state-provided support and services, family and social structures, or policies that promote or discourage social participation and mental well-being (3, 26, 27). A potential hypothesis is that the social significance of different forms of social participation is context-dependent, such that the mental health benefits of social participation vary across countries or regions. For example, in Southern European countries with stronger family networks, voluntary work may be less relevant to health than in Northern European countries, where family support roles have been replaced by formal care and the social benefits of voluntary work may be larger (28).

Building upon earlier research (29), we examined how changes in different forms of social participation predict changes in levels of depressive symptoms in older persons using fixed-effects models. In addition, we explored whether the association between various forms of social participation and depressive symptoms differs across regions of Europe.

METHODS

Study design

Data for this study were drawn from the Survey of Health, Ageing and Retirement in Europe (SHARE) (30). In SHARE, information on health, social networks, and economic factors was collected from adults aged 50 years or older using computer-assisted personal interviews. During the first wave of the study (2004/2005), 31,115 participants from 12 countries were included. The total household response rate was 62%, varying from 38.8% in Switzerland to 81.0% in France. We included respondents who entered SHARE during wave 1 (2004/2005) and were followed up in wave 2 (2006/2007) and wave 4 (2010/2011) (n = 10,706). Data from wave 3 (2008/2009) were excluded, because depressive symptoms were not assessed in wave 3. Ten countries contributed to all 3 waves of the longitudinal sample: Austria, Belgium, Denmark, France, Germany, Italy, Spain, Sweden, Switzerland, and the Netherlands.

Social participation

In each wave of SHARE, respondents were asked whether they had engaged in the following activities during the last month: 1) voluntary or charity work; 2) educational or training courses; 3) sports, social clubs, or other kinds of club activities; 4) participation in religious organizations; and 5) participation in political or community organizations. For each activity, an additional question was asked about the frequency of participation, using 4 response options: “almost daily,” “almost every week,” “almost every month,” and “less often.” In wave 4, the recall period for participation in social activities was altered to refer to the last 12 months. To maintain consistency in the recall period, our analysis focused on changes in social participation between waves 1 and 2 only.

Depressive symptoms

Depressive symptoms were assessed in all 3 waves of the study and were measured by means of the EURO-D Scale (31). The EURO-D consists of 12 items: depression, pessimism, death wishes, guilt, sleep, interest, irritability, appetite, fatigue, concentration, enjoyment, and tearfulness. Each item is scored 0 (symptom not present) or 1 (symptom present), and item scores are summed (0–12). Previous studies have demonstrated the validity of this measure against a variety of criteria for clinically significant depression, with an optimal cutoff point of 4 or above (31, 32).

Background variables

Educational level was based on the highest educational degree obtained. National levels were reclassified according to the 1997 International Standard Classification of Education into 3 categories: lower education (classifications 0–2), medium education (classifications 3–4), and higher education (classifications 5–6) (33). Countries were classified into 3 geographical regions: Northern Europe (Sweden and Denmark), Southern Europe (Italy and Spain), and Western Europe (Austria, Belgium, France, Germany, Switzerland, and the Netherlands). Marital status was defined as 1) married; 2) divorced, separated or unmarried; or 3) widowed. House-
Statistical analysis

We applied fixed-effects models (19–21) to assess whether within-person changes in social participation were associated with within-person changes in depressive symptoms. Fixed effects control for potential time-invariant confounders that vary across individuals, such as sex, family background, preexisting health, and levels of depression. In essence, fixed-effects models use each individual as his or her own control, by comparing an individual’s depression score when exposed to a given level of social participation with that same individual’s depression score when he or she is exposed to a different level of social participation. Assuming that intraperson changes in exposure are uncorrelated with changes in other variables, the difference in depression scores between these 2 periods is an estimate of the association between social participation and depressive symptoms for that individual. Averaging these differences across all persons in the sample yields an estimate of the “average treatment effect,” which controls for all stable individual characteristics. Although it does not control for time-varying factors

a Expressed as mean (standard deviation).
such as employment and marital status, these variables can be handled conventionally by incorporating them into the regression model. Fixed-effect models have 2 requirements. First, the dependent variable must be measured for each individual in a comparable fashion using a similar metric at 2 or more points in time. Second, the exposure variable of interest must change across these 2 occasions for at least a fraction of the sample (36).

Specification of our basic model was as follows:

\[
\text{EURO-D}_{it} = \mu_t + \beta_1 \text{social participation}_{it} + \beta_2 x_{it} + \alpha_i + \epsilon_{it},
\]

where EURO-D\(_{it}\) indicates EURO-D score for individual \(i\) at time \(t\), social participation\(_{it}\) is a vector of indicator variables for social participation, \(x_{it}\) is a vector of supplementary control regressors, and \(\epsilon_{it}\) is the error term. \(\mu_t\) accounts for time effects that are constant across individuals, while \(\alpha_i\) controls for time-invariant individual characteristics.

To minimize the potential impact of reverse causality, we implemented fixed-effects models that used lagged (by 4 years) social participation and examined whether changes in social participation indicators between waves 1 and 2 were associated with changes in depressive symptoms between waves 2 and 4. In the Web material, we also show results from contemporaneous models that examined the association between changes in social participation between waves 1 and 2 and changes in depressive symptoms during the same period (see Web Table 1 and Web Figure 1, available at http://aje.oxfordjournals.org/).

In addition to the fixed-effects models, we implemented a series of random-effects models. We followed standard approaches and conducted a Hausman specification test (37), which tests the null hypothesis that estimates from the fixed-effects model are not different from estimates from the random-effects model. Our results yielded a significant Hausman test result (\(P < 0.0001\)), which indicated that at conventional levels of significance, the assumption of no correlation between explanatory variables and individual characteristics was violated in the random-effects model. We report estimates from random-effects models in Web Table 2.

To calculate population-descriptive statistics, we used appropriate weights to account for the sampling design, non-response, and attrition. Weights were calibrated against the national population by age group and sex, as well as for mortality between waves. The analytical sample was limited to respondents with valid weights for the balanced panel (\(n = 9,491\)). Respondents were dropped if information was missing for depressive symptoms at wave 2 or 4 (\(n = 363\)) or for social participation at wave 1 or 2 (\(n = 132\)); this resulted in an analytical sample of 9,068 persons.
we report estimates from weighted regression analyses in Web Table 3. Because of the low efficiency in the fixed-effects models, estimates from weighted models were very imprecise; therefore, we decided to emphasize unweighted results. We applied robust standard errors to account for nonindependence clustering at the individual level. All analyses were carried out using Stata statistical software, release 13 (StataCorp LP, College Station, Texas).

RESULTS

The mean age at baseline was 63 years (Table 1). Fewer than half of respondents were male (44.9%), and about half had a lower level of education (50.6%). Educational attainment varied across European regions; the highest share of persons with lower education lived in Southern Europe (78.6%). Almost half of the study population was retired (48.3%), and 41.1% reported having difficulties making ends meet. Over 50% reported having a long-term illness; a physician’s diagnosis of hypertension was the condition reported most often (33.0%), followed by heart attack (10.3%) and diabetes (9.6%).

Levels of social participation varied markedly across regions (Table 2). Respondents from the Southern European countries reported the least participation. This difference was most pronounced for participation in sports, social clubs, or other kinds of club activities (7.5% in Southern Europe, 26.5% in Western Europe, 32.6% in Northern Europe). Although the prevalence increased slightly for several measures, social participation was very similar across the 2 waves for all regions and measures. There was great variation in the prevalence of depressive symptoms across regions, as well as over time (Figure 1). In wave 1, 26.0% of the respondents had a depressive symptom score of ≥4 points, the cutoff indicative of clinical depression symptomatology, but levels varied from 15.5% in Northern Europe to 34.6% in Southern Europe. There was a small decline in the prevalence of depressive symptoms between waves 1 and 2, whereas an increase in depressive symptoms was observed between waves 2 and 4. Within types of social participation, the lowest baseline prevalence of depressive symptoms was found for participation in political activities (18.0%) and

* Results were adjusted for social participation (mutually adjusted), age, and time.

** Results were adjusted for social participation (mutually adjusted), age, time, household size, marital status, employment status, financial difficulties, self-rated health, long-term illness, activity limitations, and physician-diagnosed diseases (heart attack, high blood pressure or hypertension, stroke, diabetes or high blood sugar, and chronic lung disease).
the highest for participation in religious activities (23.2%) (data not shown). For all types of activities, the prevalence of depressive symptoms was highest among persons who were not active.

In models that assessed the contemporaneous association between changes in social participation and depressive symptoms between waves 1 and 2 and controlled for confounders, participation in sports, social clubs, or other kinds of clubs and participation in political or community organizations predicted a decline in depressive symptoms (for sports/social clubs, $\beta = -0.102$, 95% confidence interval (CI): $-0.186$, $-0.019$; for political/community organizations, $\beta = -0.170$, 95% CI: $-0.319$, $-0.022$) (Web Table 1 and Web Figure 1). However, many of these associations did not hold in lagged fixed-effects models. As shown in Table 3, only increased participation in religious organizations was associated with a decline in depressive symptoms 4 years later, even after controlling for all confounders ($\beta = -0.190$, 95% CI: $-0.365$, $-0.016$). In addition, increased participation in political/community organizations was associated with higher depressive symptom scores ($\beta = 0.222$, 95% CI: 0.018, 0.428).

To explore whether there were differences in the association between social participation and depressive symptoms across Europe, we carried out stratified analysis by geographical region (Figure 2). There was no evidence of significant or systematic differences between European regions in these associations, although this was partly due to wide confidence intervals in each region.

**DISCUSSION**

Our findings suggest that social participation is associated with levels of depressive symptoms; however, the strength and direction of the association depend on the type of activity. Participation in religious activities was the only form of social engagement associated with a decline in depressive symptoms 4 years later. Participation in a political or community organization was instead associated with an increase in depressive symptoms. Thus, the mechanisms linking social participation to mental health in old age may differ for different activities.

Our results offer mixed support for the previously observed association between social participation and depressive symptoms (5, 6, 11, 13–15, 23–25, 39). We did not find significant associations for participation in voluntary or charity work or participation in educational or training courses. This finding seems to be in contrast with results from previous research (40, 41). In models that adjusted only for age and time, we did find contemporaneous associations between volunteering and depressive symptoms. However, these associations were not robust to control for time-varying confounding, and these activities did not predict changes in depressive symptoms 4 years later. Similarly, changes in participation in sports, social clubs, and other club activities were associated with a contemporaneous decline in depressive symptoms but did not predict changes in depressive symptoms 4 years later. A possible explanation is that short-term benefits arising from these forms of social participation diminish over time or that they reflect the impact of depression on the likelihood of participating in social activities.

Earlier research found that religiously active persons have better mental health than the religiously inactive (24, 42). Our findings suggest that this association might reflect a causal association. Participation in religious organizations may protect mental health through several pathways, including influencing lifestyle, enhancing social support networks, and offering a mechanism for coping with stress (24, 42). For example, religion has been shown to serve as a coping mechanism during a
period of illness in late life (43, 44). Through participation in religious activities, people may also become more attached to their communities, which prevents social isolation, a predictor of old-age depression. Spirituality has also been proposed as an important promoter of mental health, but this construct is not well defined, and its relationship with depression is not well understood (24). By contrast, people may not accrue the same social support, lifestyle, and coping benefits from participating in sports, social clubs, or other kinds of clubs, which may explain why these forms of social participation did not predict levels of depressive symptoms 4 years later. Although we expected stronger associations between social participation and depressive symptoms in Northern and Western European countries, the lack of regional differences in the associations across Europe supports the findings of Di Gessa and Grundy (17).

We found that participation in a political or community organization was associated with an increase in depressive symptoms 4 years later. Insights from the effort-reward balance theory may provide a partial explanation. Participation in political or community organizations could be beneficial for health when reciprocity is expected (45), which may partly explain the positive association in contemporaneous models. Respondents may experience a higher sense of reward when starting participation in a political or community organization. In the long run, however, the balance may shift towards higher effort and lower reward, which may trigger depressive symptoms. Another potential explanation for contemporaneous associations is reverse causality—that is, that depressed persons may be less likely to participate in political or community organizations. Lagged models are less susceptible to reverse causality, as they relate current changes in social participation to subsequent changes in depressive symptoms. In our study, however, there was relatively little change in participation in a political or community organization, so fixed effects may not be the best method for assessing the impact of this particular form of social participation.

Some limitations of our study should be considered. Changes in social participation may be correlated with changes in other variables associated with depressive symptoms. For example, older persons may increase or initiate participation in religious activities after the birth of a grandchild, the death of a child or sibling, or the onset of illness. The influence of several of these variables on our estimates is difficult to anticipate, however, as several of them might increase rather than decrease levels of depression, leading to underestimation of the association between participation in religious activities and depression. Another concern is reverse causation. Although we found that participation in a religious organization was associated with decreased depression scores over a 4-year period, we cannot completely rule out the possibility that this association may have been due to the impact of depression on social participation. However, sensitivity analysis that excluded respondents who had 4 or more depressive symptoms at baseline confirmed our finding for participation in religious organizations, diminishing concerns about reverse causation ($\beta = -0.306; 95\% \text{ CI: } -0.481, -0.131$). Next, as with other longitudinal studies, SHARE suffered from attrition resulting from both mortality and nonresponse. This may have led to sample selection bias, potentially compromising internal validity (30). Earlier substudies from the SHARE project showed that although health and living arrangements at baseline predicted initial survey participation and panel retention, there were no systematic differences in response and attrition rates according to key characteristics such as sex, age, and employment status (46, 47). While there is no fully satisfactory way to address this, we incorporated these and other time-varying factors into our models and focused our interpretation on these models. Finally, a limitation of fixed-effects models is that estimation is based only on the small fraction of people who change their exposure during the follow-up period. For example, between waves 1 and 2, only 6.8% of the sample changed their participation in political/community organizations, which resulted in large standard errors. Changes were more common for participation in voluntary/charity work (15.0%), education/training (11.9%), sports/social clubs (20.1%), and religious activities (10.6%).

In conclusion, our findings suggest that increased social participation is associated with depressive symptoms. However, the strength and sometimes direction of the association varies by social activity. We found that increased participation in religious activities was associated with subsequent declines in depressive symptoms, suggesting the possibility of a causal association. Our results highlight the importance of distinguishing between different types of social participation to understand how social engagement influences mental health and well-being. Further research is required to identify the specific mechanisms that explain the association between participation in religious activities and depressive symptoms. If the association is proven to be causal, however, our results suggest that policies encouraging or enabling older persons to maintain their affiliations with religious communities (e.g., by facilitating their attendance at religious events via public transport) may result in reduced levels of depressive symptoms among older persons.
