Tyrosine hydroxylase catalyses the hydroxylation of L-tyrosine to L-DOPA, the rate-limiting step in the synthesis of catecholamines. Mutations in the TH gene encoding tyrosine hydroxylase are associated with the autosomal recessive disorder tyrosine hydroxylase deficiency, which manifests phenotypes varying from infantile parkinsonism and DOPA-responsive dystonia, also termed type A, to complex encephalopathy with perinatal onset, termed type B. We generated homozygous Th knock-in mice with the mutation Th-p.R203H, equivalent to the most recurrent human mutation associated with type B tyrosine hydroxylase deficiency (TH-p.R233H), often unresponsive to L-DOPA treatment. The Th knock-in mice showed normal survival and food intake, but hypotension, hypokinesia, reduced motor coordination, wide-based gate and catalepsy. This phenotype was associated with a gradual loss of central catecholamines and the serious manifestations of motor impairment presented diurnal fluctuation but did not improve with standard L-DOPA treatment. The mutant tyrosine hydroxylase enzyme was unstable and exhibited deficient stabilization by catecholamines, leading to decline of brain tyrosine hydroxylase-immunoreactivity in the Th knock-in mice. In fact the substantia nigra presented an almost normal level of mutant tyrosine hydroxylase protein but distinct absence of the enzyme was observed in the striatum, indicating a mutation-associated mislocalization of tyrosine hydroxylase in the nigrostriatal pathway. This hypomorphic mouse model thus provides understanding on pathomechanisms in type B tyrosine hydroxylase deficiency and a platform for the evaluation of novel therapeutics for movement disorders with loss of dopaminergic input to the striatum.

Keywords: infantile parkinsonism; dopamine deficiency; catecholamine deficiency; misfolding; mislocalization

Abbreviations: BH4 = (6R)-l-erythro-5,6,7,8-tetrahydrobiopterin; 5-HIAA = 5-hydroxyindolacetic acid; HVA = homovanillic acid; l-DOPA = L-dihydroxyphenylalanine; MHPG = 3-methoxy-4-hydroxyphenylethylene glycol; THD = tyrosine hydroxylase deficiency

Introduction

Tyrosine hydroxylase (TH; EC 1.14.16.2) is a homotetrameric enzyme that catalyses the conversion of l-tyrosine to l-dihydroxyphenylalanine (l-DOPA) by using molecular oxygen as additional substrate and the cofactor (6R)-l-erythro-5,6,7,8-tetrahydrobiopterin (BH4) (Nagatsu et al., 1964; Roberts and Fitzpatrick, 2013). This hydroxylation is the rate-limiting step in the synthesis of the catecholamine neurotransmitters dopamine, norepinephrine and epinephrine (Nagatsu et al., 1964). Dopamine is distintively involved in motor control, but also in cognition, memory and reward and, as a precursor of norepinephrine and epinephrine, indirectly regulates attention and helps to maintain normal blood pressure and blood sugar (Eisenhofer et al., 2004). In the CNS, TH is mainly expressed in dopaminergic neurons of the substantia nigra, which project mostly to the striatum and have a central role in motor control, and in the ventral tegmental area, which projects to the nucleus accumbens and the prefrontal cortex and regulates motivation and reward. TH is also expressed in noradrenergic neurons of the locus coeruleus and lateral tegmental system (Zigmond et al., 1989; Bjorklund and Dunnett, 2007). Outside the CNS, TH expression is found in the adrenal medulla, the sympathetic neurons, and in non-neuronal (renal, intestine, pancreatic and lymphoid) tissues. The single human TH gene undergoes alternative mRNA splicing generating four main isoforms (hTH1–hTH4), with variations in the length of the N-terminal, where hTH4 corresponds to the longest, full-length isofrom and hTH1 to the shortest and most abundant one, equivalent to rodent TH (Nagatsu, 1995). TH activity is tightly controlled by regulatory mechanisms at the transcriptional, translational and post-translational levels (Kumer and Vrana, 1996; Tank et al., 2008). The latter includes phosphorylation at several Ser/Thr residues at the N-terminal tail (Daubner et al., 2011). Notably, phosphorylation at Ser40 by cAMP-dependent protein kinase A activates TH by releasing the feedback inhibition of catecholamines and decreasing the $K_m$ for the cofactor BH4 (Nagatsu et al., 1964). Binding of the catecholamine end-products inactivates and stabilizes TH both in vitro (Okuno and Fujisawa, 1991; Martinez et al., 1996) and in vivo (Sumi-Ichinose et al., 2001). Another short-term regulatory mechanism of TH of important biological significance is substrate inhibition, that allows steady synthesis of dopamine despite fluctuations in blood l-tyrosine (Reed et al., 2010).

Mutations in the TH gene (OMIM *191290) cause TH deficiency (THD; OMIM #605407), which is a rare disorder that comprises a broad phenotypic variation including infantile parkinsonism and l-DOPA-responsive dystonia (DRD). THD manifestations range from a mild progressive limb dystonia, postural tremor and hypokinetic rigid syndrome that is responsive to l-DOPA (termed type A) to a progressive and complex neonatal or early-infancy onset encephalopathy with l-DOPA-unresponsive parkinsonism (termed type B) (Willemsen et al., 2010). A certain genotype–phenotype correlation between the clinical subtype and the genotype of the THD patients through the in vitro TH activity of the mutant variants has recently been reported (Fossbakk et al., 2014). Nevertheless, an accurate clinical diagnosis of THD must be based on central catecholamine deficiency reflected by normal 5-hydroxyindolacetic acid (5-HIAA) but low homovanillic acid (HVA), low 3-methoxy-4-hydroxyphenylethylene glycol (MHPG) and low HVA:5-HIAA ratio in CSF from lumbar puncture (Willemsen et al., 2010), and by mutation analysis of the TH gene (Haavik et al., 2008; Kurian et al., 2011). Peripheral (urinary) concentration of catecholamines, HVA and MHPG are non-informative most probably due to dopamine production by residual TH and tyrosinase activity in non-neuronal tissues (Willemsen et al., 2010). Elevated serum prolactin may, however, be used as a peripheral biomarker reflecting central neurotransmitter status (Aitkenhead and Heales, 2013).
The release of this hormone from the pituitary gland is under control of hypothalamic dopamine, which is the primary physiological inhibitor of prolactin secretion (Ben-Jonathan, 1985). Furthermore, galactorrhoea has been observed in some severely affected hyperprolactinaemic patients with THD (Yeung et al., 2006). To date, ~70 THD patients have been reported (www.biopku.org/pnddb) (Willemsen et al., 2010; Fossbakk et al., 2014); the most recurrent TH mutation, accounting for ~30% of all mutant alleles, is c.698G>A/p.Arg233His in exon 6; NM_1999292.2 (corresponding to c.605G>A/p.Arg202His in hTH1). While as a homozygous or compound heterozygous allele this mutation can be associated with type A or type B THD (Haavik et al., 2008; Willemsen et al., 2010), about half of the patients with type B THD are homozygous for variant p.R233H (Willemsen et al., 2010).

Parkinsonian syndromes, dystonias, and related movement disorders showing a reduction in the levels of TH activity and dopamine levels are closely associated with THD (Kurian et al., 2011; Garcia-Cazorla and Duarte, 2014). Although THD is not accompanied by neurodegeneration, it shares several traits with Parkinson’s disease where the motor features actually reflect the loss of striatal dopamine due to degeneration of dopaminergic neurons in the midbrain (Obeso et al., 2010). Transgenic mouse models aiming to mimic THD by inactivating the Th gene have been generated in the past (Kobayashi et al., 1995; Zhou et al., 1995; Szczypka et al., 1999). The complete Th knock-out was non-viable, and none of the rescue mutants fully reproduced the clinical and pathological features of THD. They did, however, provide valuable insights into the importance of dopamine and the other catecholamines for mouse foetal development (Kobayashi et al., 1995; Zhou et al., 1995) and the functional interdependence of the adrenomedullary and adrenocortical systems (Bornstein et al., 2000).

To provide novel insights into catecholamine function and study the pathophysiological mechanisms responsible for the severe (type B) THD phenotype, we generated a constitutive Th knock-in mouse with the p.Arg203His mutation, equivalent to the human TH-p.R233H (hTH1-p.R202H). This mouse, here termed Th knock-in, was viable and presented with motor dysfunction due to a reduced TH activity and gradual loss of catecholamine metabolites, including dopamine. Measurements in brain extracts, immunohistochemical analyses and kinetic and molecular studies of wild-type and mutant human and mouse enzymes showed the instability of the mutant TH. Importantly, the mutant enzymes could not be stabilized by dopamine, highlighting the importance of a functional regulatory feedback inhibition by catecholamines to maintain TH levels and proper localization. Furthermore, the Th knock-in mouse displays the salient clinical features of human type B THD phenotype including biochemical markers, impaired motor function, diurnal fluctuation of symptoms and non-responsiveness to L-DOPA treatment, and thus represents an ideal model for pathomechanistic studies and for investigations of novel therapeutic approaches, such as pharmacological chaperones and treatment strategies based on circadian regulation of TH activity and/or restorative properties of sleep.

Materials and methods

Generation of the Th knock-in mouse allele

A C57BL/6 mouse carrying a constitutive knock-in of the point mutation p.Arg203His in the Th gene was custom generated by TaconicArtemis (NCBI gene ID 21823, transcript variant Th-1 NM_0093771.1; Ensembl gene ID ENSMUSG00000000214). Details on the targeting vector for electroporation, homologous recombination and selection in mouse embryonic stem cells (Art B6/3.6 background C57BL/6 NTac) are given in Supplementary Fig. 1A–C. Validation of correct and single targeting was done by Southern blot and PCR analyses (details on request). For elimination of the NeoR cassette, mice were crossed with a FLP-deleter strain [C57BL/6-Tg(CAG-Flpe)1 Arte] for random integration of the CAGGS-FLPe transgene, and subsequently mice were crossed to homozygosity.

Genotyping of Th knock-in mice

One primer set was used for testing for the presence of an additional 85 bp FRT sequence by fragment size analysis (primers ‘For’ 4601_33: 5’-GAGCTCCCAGAATTGACAGC-3’; ‘Rev’ 4601_34: 5’-GATCACACTCCACCATATCAAGG-3’) and another set for the presence of the R203H mutation via Sanger sequencing (primers 4602_35: 5’TGTCAAGTGGTA AAGTGTACC-3’ and 4602_36: 5’TGACAGCTAAAC GTCACCTCC-3’; see also Supplementary Fig. 1B and C). Standard PCR conditions were used for DNA amplification.

Mouse husbandry and treatment studies

Animal experiments were performed in accordance with the guidelines and policies of the Veterinary Office of the State of Zurich and Swiss law on animal protection, the Swiss Federal Act on Animal Protection (1978), and the Swiss Animal Protection Ordinance (1981). Animal studies received approval from the Cantonal Veterinary Office, Zurich, and the Cantonal Committee for Animal Experiments, Zurich, Switzerland. All mice are generated by back-crossing with C57BL/6J from the Jackson Laboratory (i.e. C57BL/6J, α-synuclein positive), and for controls, we exclusively used the wild-type littermates. Mice were maintained in a humidity and temperature (21–23°C) controlled environment under a 12-h dark–light cycle. For treatment studies, six tablets containing l-DOPA (levodopa 100 mg) and the decarboxylase inhibitor carbidopa (25 mg) were purchased (Sinemet) and diluted in 20 ml of double distilled H2O. For validation, the final concentration of l-DOPA was determined by high performance liquid chromatography (Blau et al., 1999).
homozygous *Th* knock-in and wild-type control mice were fed for the chronic experiments daily *per os* with a solution containing 10 mg levodopa plus 2.5 mg carbidopa per kg of body weight and per day for a time period of up to 3 weeks of age. Elevation of brain 3-OMD (3-O-methyltyrosine) and HVA control supported that mice received adequate doses of L-DOPA (Fig. 7). Treated mice were tested 24 h after the last administration for motor behaviour, and at sacrifice, tissue was collected for biochemical analyses. Mock control, independent groups of *Th* knock-in and wild-type mice, sex and age-matched, were given double distilled H$_2$O in parallel. For the acute L-DOPA treatment experiment, a group of *Th* knock-in plus wild-type control mice were first mock fed and tested for motor function (rotarod and bar test; see below). Following a resting phase of 2–3 h, all mice were loaded *per os* with a single bolus of a solution containing 10 mg levodopa plus 2.5 mg carbidopa per kg of body weight, before retesting these mice for motor coordination within 20–45 min after the L-DOPA loading.

**Metabolic cage analysis**

Locomotion, food and water intake, O$_2$ consumption and CO$_2$ production were determined for single housed mice (females at the age of 9 months) during a 24-h period in metabolic cages in an open-circuit indirect calorimetry system as previously described (Wueest et al., 2014) (PhenoMaster, TSE Systems). After being adapted to single caging, mice were placed in cages closed with air-tight lids. Water bottles and food cups were placed on scales to measure water and food intake continuously. The measurements were saved on a computer in 20-min intervals and used to calculate cumulative food and water intake. Activity data were measured using an infrared light-beam. To measure energy expenditure and respiratory exchange ratio (RER), ambient air was pumped through the cage via a flow controller. Air entering and leaving each cage was monitored (RER), ambient air was pumped through the cage via a flow controller. The cages were connected to two analysers measuring O$_2$/CO$_2$ concentration of each cage for a period of 2 min in 20-min intervals. Energy expenditure and respiratory exchange ratio were calculated using the manufacturer’s software based on the following equation:

\[
\text{energy expenditure (kcal/h)} = \frac{3.941 \times \text{VO}_2 + 1.106 \times \text{VCO}_2}{1000};
\]

\[
\text{respiratory exchange ratio} = \frac{\text{VCO}_2}{\text{VO}_2}.
\]

**Behavioural motor testing**

Experiments were carried out during the light phase, between 10 am and 5 pm, and always at the same time of the day within the same group of animals. Experimental batches were acclimated to the test room for at least 1–2 days before testing.

**Open field test**

For the open field test (Bello et al., 2011), Plexiglas activity boxes monitored by a video tracking system (Ethovision, Noldus) were used to assess total horizontal activity and mean velocity of locomotion. Animals were placed in a neutral position of the acrylic boxes (40 x 40 x 46 cm) and left to explore freely and undisturbed for 30 min. Boxes were carefully cleaned between tests to minimize odour cues in the arena.

**Bar test**

For the Bar test (Noain et al., 2013), spontaneous catalepsy was determined in *Th* wild-type and *Th* knock-in mice using the horizontal bar test in which the time of immobility (defined as immobile trunk and limbs) was assessed as described previously. Briefly, to discard the possibility of confounding freezing behaviour induced by fear/stress with catalepsy, all mice were habituated to the experimental context by 2 min free exploration over the working bench and experimental setup. Following this, mice were restrained by the tail, their front paws placed over the 5-cm elevated bar (1-cm diameter, plexiglas) and the back limbs set over the working bench. Immediately after, the timer was started. A trial was considered valid when the animal remained grabbing the bar with the front paws until the timer was running (~2 s). Usually, 2–4 trials were invalid for each mouse at the beginning of the testing session. The highest immobility score out of five valid trials was considered for the analysis of both wild-type and knock-in subjects. The cut-off of the experiment was set at 180 s.

**Rotarod test**

For the Rotarod test (Avale et al., 2004), wild-type and *Th* knock-in mice were individually placed in a neutral position on the immobile rotarod treadmill (UgoBasile). Immediately, the speed was increased to 16 rpm and each mouse was given a 10-min training session. During the training session mice were repositioned on the rod after each fall. Mice were tested 3 h later for 3 min at a fixed velocity of 16 rpm, and the latency to the first fall was recorded for each subject.

**Gait analysis**

For gait analysis (de Medinaceli et al., 1982; Kunkel-Bagden et al., 1993; Suresh Babu et al., 2012), both hind and fore paws of mice were inked with non-toxic blue and red ink. Animals were immediately placed at one end of a 30-cm acrylic alley, whose floor was covered in white absorbent paper, and encouraged to walk to the opposite end. The paper was then removed and labelled with the animal ID number for further analysis. The stride length and width were manually measured and normalized to body weight (‘size’) of each mouse to obtain short-step and wide-based gait indices, respectively.

**Preparation of whole brain lysates from mice**

Immediately after sacrifice, whole brains were resected and shock frozen in liquid nitrogen. Frozen brains were grinded to powder under liquid nitrogen; thereafter, all procedures were carried out at 4°C. Powdered brains were ‘dissolved’ in 1 ml of homogenization buffer containing 50 mM Tris-HCl, pH 7.5, 100 mM KCl, 1 mM dithiothreitol (DTT), 0.2 mM PMSF (stock 10 mg/ml in isopropanol), 1 μM leupeptin.
Gene (mRNA) expression studies

Total RNA was extracted from powdered mouse brains by the QiAmp RNA Blood Mini Kit (Ref. 52304; Hombrechtikon) and cDNA was produced by the Promega reverse transcription system (Ref. nr. A3500). Mouse Th, Tph1, Tph2 and Igf1 mRNA expression levels were performed using the commercially available ABI assays (Mm.00447546 for Th mRNA; NCBI RefSeq NM_009377.1; Mm00493798_m1 for Tph1 mRNA, NCBI RefSeq NM_001111274.1, NM_009414.2; Mm00557717_m1 for Tph2 mRNA, NCBI RefSeq NM_173391.2; Mm00439560_m1 for Igf1 mRNA, NCBI RefSeq NM_001111274.1). The murine glyceraldehyde-3-phosphate dehydrogenase (Gapdh) mRNA (ABI assay ID: Mm99999915_g1; NCBI RefSeq NM_001111274.1) was used to normalize the relative Th, Tph1, and Tph2 mRNA levels. Values were calculated as described (Livak and Schmittgen, 2001).

Determination of protein, neopterin, biopterin and monoamine neurotransmitter metabolites

Protein concentration (in g/l) was determined by using the M-Tp Mikroprotein kit from Beckman Coulter Synchron LX-System (Beckman Coulter Inc; kit-no. 445860). Biopterin, neopterin and monoamine neurotransmitter metabolites were determined in brain tissue following published protocols (Blau et al., 1999; Elzaouk et al., 2003).

Total thyroxine, thyroid stimulating hormone and prolactin

Serum IGF1 was determined by radioimmunoassay (RIA) using a rat IGF1 RIA kit (DSL-2900, Bühmann Laboratories) (Elzaouk et al., 2003), total thyroxine from whole blood dried on filter paper was measured with the ‘GSPTM Neonatal Thyroxine kit’ from PerkinElmer (Life and Analytical Sciences), serum prolactin was quantified using an ELISA kit for mouse and rat (GenWay Biotech, Inc), and glucose was measured according to standard methods on a routine Clinical Chemistry unit on a Beckman Coulter UniCel® DxC 600 (Nyon) following the manufacturer’s instructions.

Measuring blood pressure in mice

A non-invasive computerized tail-cuff system for measuring systolic blood pressure in mice was applied as described (Krege et al., 1995).

Results

Th knock-in mice display moderate growth retardation and hypotension

A constitutive knock-in containing the Th-p.Arg203His was generated by homologous recombination in the C57BL/6 background and bred to homozygosity (Supplementary Fig. 1 and Supplementary Table 1). The Th knock-in litter size was normal with an expected Mendelian ratio and an apparently normal phenotype initially. After weaning, however, Th knock-in mice exhibited moderate and continuous growth retardation with 25–34% less body weight compared to their wild-type or heterozygous litters (Fig. 1A and B). That this was not due to feeding abnormalities was confirmed quantitatively by metabolic cage analyses showing normal food intake and respiratory exchange ratio. Locomotor activity and energy expenditure were, however, reduced (Supplementary Fig. 2). Follow-up examinations of mutant mice revealed no
constipation, and a quantitative analysis of the fat and total energy contents in faeces also revealed no differences between wild-type and Th knock-in mice, indicating that mutant mice had normal absorption and digestion (data not shown). Th knock-in was normoglycaemic and Igf1 gene expression was normal (mRNA of whole brain extracts; not shown) as were IGF1 serum levels in adult mice at the age of 12 weeks (Supplementary Fig. 3A). We noticed however that Igf1 mRNA was significantly elevated in whole brain extracts from Th knock-in mice at the age of 3 weeks (not shown), implying that the IGF system might be involved in brain growth, as suggested by others (Delafontaine et al., 2004). We further detected elevation of the total thyroid hormone thyroxine (Supplementary Fig. 3B) and hypotension (Supplementary Fig. 3C) while serum thyroid stimulating hormone was not different between mutant and control mice (not shown).

Both low body weight and reduced blood pressure are found in patients with type B THD (Grattan-Smith et al., 2002; Willemsen et al., 2010) and in mice with norepinephrine and epinephrine deficiency (Swoap et al., 2004), while we found normal levels of catecholamines in the adrenals and heart of adult Th knock-in mice (data not shown), which indicated central regulation for reduced body weight and hypotension. Normal catecholamine content in peripheral tissues was also reported for heterozygous Th knock-out mice that present a significant reduction of TH (Kobayashi et al., 1995).

**Figure 1** Sex-specific differences in body weight between wild-type and Th knock-in mice. (A) Female and (B) male mice fed ad libitum with standard chow. Growth retardation resulted in reduced body weight, for instance at the age of 12 weeks 25% reduction for females and 34% reduction for males. Significant differences between Th knock-in (ki) and wild-type (wt) combined with heterozygotes mice are indicated: ****p < 0.001; *****p < 0.0001 (Student’s two-tailed t-test).

**Gradual loss of brain catecholamines in Th knock-in mice**

Whole brain catecholamine and serotonin metabolites were measured in newborn (Day 1), juvenile (3 weeks) and adult...
mice (12 weeks and 1 year). The values of brain dopamine and other catecholamines and their metabolites obtained for adult wild-type mice were in a similar range to those obtained in previous studies (Thöny et al., 2008; Calvo et al., 2010). HVA, the major biomarker in CSF for TH deficiency in patients, was low in Th knock-in mice at all ages, whereas L-DOPA, dopamine, norepinephrine and MHPG were initially normal, but fell continuously thereafter in mutant mice (Fig. 2A–D). This decrease appears specific for the catecholamines and their metabolites, as serotonin, which is typically not compromised in THD, remained unchanged both with respect to age and when compared with the values in wild-type mice, and only at an advanced age, when mutant mice exhibited a striking loss of catecholamines, was a reduction of the serotonin precursor 5-hydroxytryptophan (5-HTP) observed (Fig. 2D). Biopterin (and neopterin) content remained unchanged at all ages (Supplementary Fig. 4), as was the case for 5-HIAA, thus leading to a reduced HVA:5-HIAA ratio in Th knock-in mice compared to wild-type mice at all ages (Supplementary Table 2), similar to what is found in the CSF of THD patients (Willemsen et al., 2010). Furthermore, we measured a consistent elevation of serum prolactin levels in adult mutant mice reflecting central dopamine deficiency (Supplementary Fig. 3D) that caused reduced fertility of Th knock-in females (not shown), although galactorrhoea was not observed.

**Early motor dysfunction and diurnal fluctuation of the motor deficits in Th knock-in mice**

A moderate reduction of motor activity was observed in mutant mice during metabolic cage analyses (Supplementary Fig. 2C). To explore the nature of this motor dysfunction, we performed a series of behavioural tests assessing spontaneous catalepsy, motor coordination, amount and velocity of spontaneous locomotion, and gait characteristics at different ages. Motor function was tested in juvenile (3 weeks old), young adult (11 weeks old) and 1-year-old mutant male mice plus sex and age-matched wild-type controls (Fig. 3A–F). In the bar test, Th knock-in mice showed increased time of immobility compared to controls, indicating spontaneous catalepsy, a sign of rigidity and inability to initiate movements. In addition, when placed at the bar, Th knock-in mice of all ages, but particularly older adults, presented an abnormal body posture and muscle twitching, suggesting the presence of a dystonic component, while we did not observe clasping of the hindlimbs by the vertical tail suspension assay as a common test for a dystonic phenotype in mice (Sato et al., 2008). Th knock-in male mice challenged in the rotarod test showed a significantly reduced latency to fall, indicating impaired motor coordination. In the open field test,
Th\textsuperscript{k} knock-in mice showed significantly reduced levels of horizontal activity (amount and velocity of spontaneous locomotion), indicating a hypokinetic and bradykinetic phenotype. Next, we analysed the characteristics of gait (normalized to body weight to compensate for the size difference between genotypes). Mutant mice had an increased stride width per body weight index compared to normal controls, suggestive of a significant wide-based gait. This was confirmed by a generalized disorganization of the gait, including dragging marks, changes in direction and freezing (data not shown). In contrast, Th\textsuperscript{k} knock-in mice did not show abnormal stride length, as observed by an unchanged stride length per body weight index compared to controls. In summary, while the catecholamine deficiency increased with age (Fig. 2A–D), the severe motor dysfunction was present from the first measurements at 3 weeks onwards, and its severity appeared independent of age.

Figure 3 Motor function tests of mutant (Th\textsuperscript{k} knock-in) and wild-type (Th\textsuperscript{wt}-wild-type) male mice at different ages. (A) Bar test for assessment of catalepsy. (B) Rotarod test for determination of motor coordination. (C) Total distance travelled in the open field test. (D) Mean velocity of locomotion in the open field test. (E) Gait analysis to test for stride width normalized to body weight. (F) Gait analysis to test for short-step disorder (stride length normalized to body weight). Th\textsuperscript{wt}-wild-type mice are shown in black and Th\textsuperscript{k} knock-in in grey. Significant difference from the corresponding wild-type value is indicated: **p < 0.01; ***p < 0.001 (Student's two-tailed t-test or ANOVA for fluctuation bar test).
Marked diurnal fluctuation of motor behaviour is a hallmark in patients with THD (Willemsen et al., 2010; Haugarvoll and Bindoff, 2011). To determine whether the motor performance in mutant mice varied throughout the day, we performed the bar test at 8 am and 8 pm in the same set of animals and found that Th knock-in mice performed significantly better after the resting period (at 8 pm, note the inverted circadian rhythms of mice compared to humans) than after the activity period (at 8 am), while wild-type controls presented a stable performance at both times (Willemsen et al., 2010; Haugarvoll and Bindoff, 2011) (Fig. 4).

**Gradual reduction of TH protein and activity in brain of Th knock-in mice, with specific loss of TH in striatum**

Gene expression of Th, Tph1 and Tph2 (mRNAs) in whole brain extracts of Th knock-in mice was similar to that in wild-type mice at different ages, and no particular heterogeneity was observed for transcript numbers in either mice. Th mRNA transcripts (but not Tph1 and Tph2 mRNAs) showed an increase of ~50% from newborn (1 day) to 3 weeks for both wild-type and Th knock-in mice (Supplementary Table 1). On the other hand, immunoquantification of TH protein content in whole brain extracts showed a remarkable 5-fold increase in TH relative to total protein from newborn to 3 weeks in normal mice, but no significant increase in TH protein was measured in this period for Th knock-in (Fig. 5A and B). For wild-type mice, TH content was maintained from 3 weeks up to 1 year, but Th knock-in revealed a gradual loss of TH protein relative to the normal (wild-type) content, reaching a value as low as ~3% of wild-type TH protein in 1-year-old animals (Fig. 5B, inset). The specific TH activity in brain extracts under standard conditions, measured by a sensitive radiochemical assay (Reinhard et al., 1986), also followed a similar development as the protein content for the wild-type animals (the activity increased from 1.6 ± 0.6 to 5.3 ± 1.0 pmol 1-DOPA/mg/min from Day 1 to 3 weeks, a value that was maintained up to 1 year). However, the activity in Th knock-in brain extracts was below the sensitivity threshold and could not be determined accurately by the radiochemical assay or other methods tested, including HPLC and fluorimetric detection of L-DOPA (Haavik and Flatmark, 1980).

Loss of TH was also observed by immunohistochemical staining for TH of the substantia nigra pars compacta and ventral tegmental area region and corpus striatum on coronal brain sections from perfused adult male Th knock-in and wild-type mice (6–7 months old). As seen in Fig. 5C we observed a similar expression pattern of TH in Th knock-in and control mice in the substantia nigra pars compacta/ventral tegmental area, with some less dense stained projections, whereas in the corpus striatum we observed an almost complete lack of immunoreactive processes. Furthermore, higher magnification photomicrographs depict a similar soma staining in the midbrain of mutants and controls whereas reduced staining of processes is again observed for the mutants (Fig. 5D). A semiquantitative TH+ cell count performed in the substantia nigra pars compacta/ventral tegmental area region of mutant and control brains indicated no decrease of immunoreactive TH cells in the midbrain of the mutants (220.5 ± 35.5 and 232.5 ± 35.5 for Th knock-in and Th wild-type mice, respectively). Together with the lack of aberrant amyloid deposition in either midbrain or corpus striatum, as indicated by Congo red staining in these brain areas (Fig. 5E), the histological results strongly support lack of neurodegeneration in the midbrain of mutant animals. Rather, our results support the reduction in the amount of TH protein measured by immunoquantification and revealed a marked mislocalization of TH, consistent with a defective transport of mTH-R203H across the nigrostriatal projection (see below).

**The misfolding loss-of-function mutations hTH1-R202H and mTH-R203H are not stabilized by dopamine**

To better understand the TH dysfunction in THD patients and in Th knock-in mice, we studied the molecular and kinetic effects of the mutation in the human (h) and mouse (m) TH enzymes, using purified, tetrameric,
recombinant hTH1-wt, mTH-wt, hTH1-R202H and mTH-R203H. First we analysed the substrate and cofactor-dependent activity of each enzyme (Supplementary Fig. 5A and B); the steady state activity constants are summarized in Table 1. Compared with hTH1-wt, mTH-wt showed reduced specific activity, but a similar $K_{m}(\text{BH}_4)$, slightly decreased $S_{0.5}(\text{L-Tyr})$ (higher substrate affinity for L-Tyr) and reduced substrate inhibition constant ($K_{si}$), denoting stronger substrate inhibition. The mutants hTH1-R202H and mTH-R203H showed decreased $V_{\text{max}}$ and $K_{m}(\text{BH}_4)$ and slight increase of $S_{0.5}(\text{L-Tyr})$ compared with their corresponding wild-type counterparts, indicating a clear, but not severe kinetic defect. On the other hand, an evident destabilizing misfolding of the mutant enzymes was indicated by a 10-fold lower yield of purified tetrameric mutant enzymes expressed in E. coli, compared with the wild-type forms. Decreased protein stability of the hTH1-R202H mutant is also predicted by the FoldX algorithm.

(Schymkowitz et al., 2005), which estimated a destabilization energy of 9.96 kcal/mol (ΔΔG) based on the tetrameric structure of hTH (PDB 2XSN), including the catalytic and tetramerization domains. To corroborate that the mutation caused the destabilization, we performed differential scanning fluorimetry (DSF) analyses. This method was chosen due to the small amounts of protein required, as protein was limited for the mutants. The mutant enzymes showed reduced stability compared with the respective wild-type forms [2–3°C decreased midpoint denaturation (T_m)-values; Fig. 6A]. Although significant, the decreased thermodynamic stability caused by the mutation could not, however, fully explain the relative decay of TH protein in the Th knock-in compared to the wild-type mouse (Fig. 5). Additional defects in regulatory stabilization of the mutant mTH-R203H enzyme might explain this relative loss of TH protein in the mutant mouse. Stabilization of TH by dopamine and other catecholamines is an important regulatory mechanism, which leads to competitive inhibition of TH activity versus the BH_4 cofactor, and provides a natural chaperone effect that prevents degradation of the enzyme (Okuno and Fujisawa, 1991; Sumi-Ichinose et al., 2001; Thöny et al., 2008). In vitro, this stabilization is manifested by an increase in the T_m-values and a decrease in its susceptibility to proteolysis (Martinez et al., 1996; McCulloch and Fitzpatrick, 1999). As expected, hTH1-wt and mTH-wt were stabilized by dopamine binding, increasing their T_m-values up to 3°C (Fig. 6A and B), but the mutants were not stabilized by dopamine (Fig. 6C and D). In addition, dopamine protected the wild-type enzymes, but not the mutants, from limited tryptic proteolysis (shown for hTH1 in Fig. 6E–K).

### Non-responsiveness of Th knock-in mice to L-DOPA treatment

We determined the effect of chronic and acute L-DOPA treatment on the motor outcome of juvenile or young adult Th knock-in mice and controls. In the chronic tests, catalepsy and motor coordination were investigated after daily L-DOPA (plus carbidopa) or mock treatment from birth to 3 weeks of age using a high dose according to recommendations for THD in humans (i.e. 10 mg/kg/day of L-DOPA) (Willemsen et al., 2010). No significant differences were found either in the bar test or rotarod performance in Th knock-in mice given L-DOPA or vehicle (Supplementary Fig. 6A and B). Similar negative results were obtained from treating adult Th knock-in mice over a period of 12 days (not shown). Nevertheless, monoamine neurotransmitter analysis in brain extracts of sacrificed mice showed significant metabolite improvement following L-DOPA treatment (Fig. 7A), although TH protein was not increased (Fig. 7B). Similarly, in an acute test for motor coordination (rotarod) and catalepsy or rigidity (bar test) upon a single dose of L-DOPA (10 mg per kg body weight plus carbidopa), Th knock-in mice did not show any differences in performance before and 20–45 min after administration (Supplementary Fig. 6C and D), corroborating non-responsiveness of Th knock-in mice to L-DOPA treatment.

### Discussion

The Th knock-in mouse was generated to provide an experimental in vivo model to investigate TH and catecholamine deficiency both in terms of disease pathogenesis and the effect of mutations on enzyme function and regulation in vivo. In the longer term, this model appears valuable to test treatments aimed at improving diseases related to loss of dopamine. The model is clinically robust. The Th knock-in mouse appears normal at birth, but thereafter exhibits moderate failure to thrive, motor abnormalities including abnormal body posture and twitching, i.e. dystonia-like features, reduced coordination, hypokinesia, ataxia and catalepsy or rigidity-akinesia. There is also clear diurnal variation of the motor defects and lowered blood pressure, as found in THD patients homozygous for p.Arg233His (Willemsen et al., 2010). The biochemical and other abnormalities in the Th knock-in mice include an early and persistent decrease in brain dopamine and noradrenaline to critically low levels, associated with low brain TH, which together with a
reduced body weight and hyperprolactinaemia are characteristics of THD. Th knock-in mice were notably homogeneous with respect to all parameters determined in this work, including motor dysfunction, biochemical phenotype and unresponsiveness to L-DOPA, which probably reflects the genetic background homogeneity of these inbred strains. Patients homozygous for p.Arg233His actually show higher phenotypic variability (Willemsen et al., 2010), which might point to THD as a complex trait autosomal recessive disorder where the phenotype might be modulated at different steps of the catecholaminergic systems, reflecting a higher complexity in human than mice.

Previous mice models have not mirrored THD to the same degree as the here presented Th knock-in mouse. Both the Th<sup>−/−</sup> and the dopamine β-hydroxylase-deficient Dbh<sup>−/−</sup> knock-out mice have a high pre- and perinatal mortality due to cardiovascular failure associated with the lack of norepinephrine, and confirm the importance of catecholamines for foetal development (Kobayashi et al., 1995; Thomas et al., 1995; Zhou et al., 1995). TH function and norepinephrine synthesis could be rescued in noradrenergic neurons of transgenic Th<sup>−/−</sup> mice. These dopamine-deficient mice survive for a short period without treatment (Willemsen et al., 2010; Garcia-Cazorla and Duarte, 2014), but have normal norepinephrine levels and are thus imperfect models for THD. The aromatic amino acid decarboxylase knock-out mouse is catecholamine-deficient and shows a 50% survival, but shows in addition seriously reduced serotonin levels (Lee et al., 2013) and is also not a model to investigate the pathogenic mechanisms of specific TH deficiency.

Newborn Th knock-in mice show normal values of catecholamines and other metabolites, except for a reduction in HVA. By 3 weeks of age, however, we observed a drop in brain norepinephrine that, despite its crucial role in mouse foetal development (Thomas et al., 1995), did not affect pup survival. Initially, the reduction in norepinephrine was not accompanied by any significant decrease in dopamine, pointing to compensatory mechanisms that maintain dopamine levels e.g. by downregulation of its

Figure 6 The stability of recombinant purified human TH1 (hTH1) and mouse TH (mTH) and the respective mutants R202H and R203H, and effect of dopamine. (A–D) Differential scanning fluorimetry profiles (fluorescence at 610 nm versus temperature) for hTH1-wt (A), mTH-wt (B), hTH1-R202H (C) and mTH-R203 (D), analysed at a concentration of 0.9 μM subunit without (solid black line) and with (dotted line) equimolar amount (0.9 μM) of dopamine. The midpoint denaturation (T<sub>m</sub>)-values, determined as maximal temperature in first-derivatives, are shown in the corresponding plots. (E) SDS-PAGE showing the limited tryptic digestion of hTH1-wt (lanes 1–5) and hTH1-R202H (lanes 6–10) in the absence (2, 3, 7, 8) and the presence (4, 5, 9, 10) of 50 μM dopamine; 1 and 6 are the respective controls in the absence of trypsin. Conditions: 2.5 μM subunit hTH1 or hTH1-R202H were incubated with trypsin for 30 s (2, 4, 7, 9) or 60 s (3, 5, 8, 10) at 25°C, at a TH:trypsin ratio of 200:1. The gels were stained with Coomassie Brilliant Blue and the raw area of the bands was measured using the Image Lab 3.0.1 software, and represented for lanes 1, 3, 5, 6, 8 and 10 in F, G, H, I, J and K, respectively. At the selected conditions, hTH1-wt (apparent molecular weight of 59 kDa), was trypsinized into two truncated forms of 57 and 54 kDa, both lacking the N-terminal peptide MPTPDATTPQAKGFR (analyses by LC–MS/MS spectroscopy; data not shown).
degradation (Tunbridge et al., 2006). Concomitant to their defective brain noradrenaline content, Th knock-in mice fail to accomplish the 5-fold increase in TH protein observed for the Th wild-type mice from newborn to 3 weeks of age (Fig. 5B), despite the presence of normal (similar to wild-type) levels of Th-mRNA (Supplementary Table 1). A similar substantial increase in TH in the same postnatal period has been reported, and this increase appears critical for the correct development of the dopaminergic system and the psychomotor function (Homma et al., 2011). This finding is supported by our results showing early and persistent motor dysfunction in the Th knock-in mice. The postnatal increase in TH protein in normal mice is not only driven by upregulated transcription (Supplementary Table 1) but through stabilization of the TH protein, where both the level of BH₄ and catecholamines themselves have been shown to be implicated in the stabilization (Homma et al., 2011, 2013). BH₄ levels are similar in Th wild-type and knock-in mice, and the $K_m$(BH₄) for the mutant enzymes indicates a relative high affinity for the cofactor (Table 1). Catecholamine binding and feedback inhibition of TH occur in competition with BH₄ (Nagatsu, 1995; Daubner et al., 2011), and thus the enzyme kinetics data are in accord with a mutation-associated structural change in TH that leads to opposite effects for BH₄ and dopamine, and to defective stabilization by dopamine (or norepinephrine; data not shown). Despite some recent insights on residues important for catecholamine binding at the catalytic domain (Briggs et al., 2014), a structural explanation for the defective stabilization by dopamine in the mutants must await the determination of high resolution structures of full-length TH, including the regulatory domain, where the determinants for high affinity binding are located (McCulloch and Fitzpatrick, 1999; Nakashima et al., 1999). The hTH-R202H and mTH-R203 mutants show both kinetic (Table 1) and stability defects (Fig. 6), but the lack of dopamine stabilization of mutant TH emerges as a deleterious regulatory deficiency that explains the lack of accumulation of TH protein in the critical postnatal period in the Th knock-in mice (Fig. 5A and B). Defective stabilization by catecholamines may also support the specific deficit of TH expression in the striatum (Fig. 5C and D) as proper transport of TH to this brain area also requires the stabilization of the enzyme (Homma et al., 2013). Mutation-associated defective trafficking and aberrant localization of protein cargos is a recurrent pathological mechanism in neurological and neurodegenerative disorders (Hung and Link, 2011; Encalada and Goldstein, 2014). Little is known about mechanisms of transport of TH and dopamine in the dopaminergic nigrostriatal pathway projecting from the substantia nigra pars compacta to the caudate-putamen (striatum), although it is accepted that at least in adrenergic neuronal systems, TH is fast transported along the axon in an anterograde fashion to the terminals (Brimijoin and Wiermaa, 1977). Accordingly, impaired axonal transport of TH in dopaminergic projections has recently been shown to be associated with parkinsonism and drastic
reduction of TH and dopamine levels in striatal synapses (Ittner et al., 2008). It is thus very probable that the observed motor dysfunction in the Th knock-in mice is caused by defective TH protein transport leading to scarce TH and dopamine in synaptic terminals to activate dopamine receptors in the caudate-putamen.

Lack of or poor responsiveness to L-DOPA is manifested by a large number of patients with THD type B, particularly those with the hTH1-R202H mutation (Grattan-Smith et al., 2002; Willemsen et al., 2010). One interesting finding of the present study is that the motor dysfunction of the Th knock-in mouse is not improved by standard L-DOPA supplementation even when treated from the first day of life. Other mouse models with dopamine deficiency show a partial recovery with dopamine treatment, especially in features such as feeding problems. Motor improvement is, however, often incomplete (Zhou and Palmiter, 1995), reflecting perhaps the developmental deficiencies in the foetal and perinatal periods (Zhou and Palmiter, 1995; Homma et al., 2011). Possible neurodevelopmental disorders associated with defective stabilization by catecholamines and consequent mislocalization of TH cannot be ruled out as the reason for the lack of DOPA-responsiveness of the motor dysfunction in the Th knock-in mice, despite the apparent correction of L-DOPA levels and increase of dopamine in brain extracts observed after treatment (Fig. 7). Developing novel non-L-DOPA-based therapeutic strategies for THD type B may thus be an attractive approach, especially for patients with the specific hTH-R233H mutation. In this respect, emerging therapies based on protein stabilization, e.g. pharmacological chaperones, appear promising, as we have previously shown in in vitro experiments that the variant hTH1-R202H can be stabilized by compounds with chaperone potential (Calvo et al., 2010; Hole et al., 2015). Furthermore, the diurnal fluctuation of motor deficits is definitively an important hallmark of our Th knock-in mutant mouse and may also be exploited in the search for novel treatment strategies based on the restorative potential of either circadian regulation of TH activity and/or restorative properties of sleep.

Finally, the growth retardation measured in the Th knock-in mutant mouse in combination with normal food intake, normoglycaemia and apparent reduced energy expenditure in the metabolic cage deserves explanation. Surviving mice with selective dopamine deficiency in dopaminergic neurons, but not in noradrenergic neurons, exhibit abnormal feeding behaviour including swallowing difficulties (aphagia) (Zhou and Palmiter, 1995; Szczypka et al., 1999), symptoms we did not observe in the Th knock-in mice. On the other hand, growth retardation in combination with normal food intake has also previously been found in total and neuron-specific dopamine-receptor knock-out mice, which shows reduced dopamine signalling (Baik et al., 1995; Noain et al., 2013). Like these other surviving TH-deficient mice with reduced noradrenergic activity, the Th knock-in mice presented here showed lowered resting metabolic rate with respect to wild-type mice. Furthermore, it has become increasingly clear that isolated dopaminergic abnormalities and parkinsonian syndromes involve abnormal or increased energy expenditure during walking and motor tasks which may explain the reduction in growth of mutant mice despite comparable food intake with wild-type mice (Molero-Luis et al., 2013; Amano et al., 2014).

In conclusion, there is a large spectrum of phenotypes in patients with THD, resulting from diverse deficiencies in absolute and relative dopamine and norepinephrine levels with different impact on systemic and motor function (Willemsen et al., 2010). This variability would depend on the catalytic, conformational and regulatory defects of the particular TH mutation. In agreement with severely affected patients homozygous for the mutation p.R233H, Th knock-in mice studied in this work present severe motor deficiencies from a juvenile age onwards, and these abnormalities are apparently not corrected by classical replacement treatment with L-DOPA. The mutant hTH1-R202H and mTH-R203H proteins are not stabilized by dopamine, leading to intracellular instability, gradual loss of TH activity and altered nigro-striatal distribution, aiding to interpret the biochemical and locomotor phenotype of Th knock-in. In addition, to contribute to the understanding of the biochemical pathogenesis of catecholamine deficiency, this mouse model offers a useful platform for designing and evaluating new routes to disease therapies not only for THD, but also other genetic and idiopathic dopaminergic deficiencies.
