A 28-year-old, white, male wildlife biologist presented with multiple skin lesions on his left hand and forearm. These lesions varied in size from that of a penny to that of a quarter (i.e., 10–20 mm). The patient had been working with Desert Bighorn Sheep, *Ovis canadensis*, in the Silver Bell Mountains of Pima County, Arizona. He physically subdued these sheep by hand. Before doing this, he would spray his flight suit, hands, gloves, and other equipment with chlorhexidine. Six weeks after starting this job in January 2004, he developed multiple raised, nonerythematous, pruritic nodules on his left hand (figures 1 and 2). The patient had had no other associated symptoms. He had no significant past medical history, was not taking any medications, and had an unremarkable family and travel history. The findings of a physical examination were unremarkable, except for the aforementioned skin lesions. The skin lesions resolved ~2 weeks after their appearance without receipt of therapy, leaving scarring at the site of the lesions.

What is your diagnosis?
