Aims To evaluate the effects of cardiac resynchronization therapy (CRT) on long-term survival of patients without baseline left ventricular (LV) mechanical dyssynchrony.

Methods and results A total of 290 heart failure patients (age 67 ± 10 years, 77% males) without significant baseline LV dyssynchrony (<60 ms as assessed with tissue Doppler imaging) were treated with CRT. Patients were divided according to the median LV dyssynchrony measured after 48 h of CRT into two groups. All-cause mortality was compared between the subgroups. In addition, the all-cause mortality rates of these subgroups were compared with the all-cause mortality of 290 heart failure patients treated with CRT who showed significant LV dyssynchrony (≥60 ms) at baseline. In the group of patients without significant LV dyssynchrony, median LV dyssynchrony increased from 22 ms (inter-quartile range 16–34 ms) at baseline to 40 ms (24–56 ms) 48 h after CRT. The cumulative mortality rates at 1-, 2-, and 3-year follow-up of patients with LV dyssynchrony ≥40 ms 48 h after CRT implantation were significantly higher when compared with patients with LV dyssynchrony <40 ms (10, 17, and 23 vs. 3, 8, and 10%, respectively; log-rank P < 0.001). Finally, the cumulative mortality rates at 1-, 2-, and 3-year follow-up of patients with baseline LV dyssynchrony were 3, 8, and 11%, respectively (log-rank P = 0.375 vs. patients with LV dyssynchrony <40 ms). Induction of LV dyssynchrony after CRT was an independent predictor of mortality (hazard ratio: 1.247; P = 0.009).

Conclusion In patients without significant LV dyssynchrony, the induction of LV dyssynchrony after CRT may be related to a less favourable long-term outcome.

Keywords Heart failure • Echocardiography • Cardiac resynchronization therapy • Prognosis

Introduction Cardiac resynchronization therapy (CRT) is currently indicated for patients with drug-refractory heart failure, left ventricular ejection fraction (LVEF) ≤35%, and wide QRS complex (≥120 ms).¹² Observational studies have shown that the presence of significant left ventricular (LV) mechanical dyssynchrony (as assessed with different imaging techniques) is related to a favourable response to CRT and improved outcome.³⁻⁴ Indeed, restoration of LV synchronicity by biventricular pacing has been related to LV reverse remodelling, decrease in mitral regurgitation, and improvement in clinical outcome.⁸ In contrast, lack of significant LV mechanical dyssynchrony has been related to a high rate of non-response to CRT.⁹¹⁰ As much as 30% of heart failure patients presenting with a wide QRS complex do not show LV mechanical dyssynchrony.¹¹ It has been suggested that CRT could induce LV mechanical dyssynchrony in this subgroup of patients, leading to impaired LV performance and, subsequently, poor clinical
outcome. However, to date, no study has evaluated the potential induction of LV mechanical dyssynchrony after CRT implantation in this subgroup of patients and, more important, the long-term clinical consequences of this acutely induced LV dyssynchrony remain unknown. Accordingly, the aims of the present study were:

(i) to evaluate the acute effects of CRT on LV synchronicity in heart failure patients fulfilling the current inclusion criteria for CRT but without baseline LV mechanical dyssynchrony;

(ii) to study the impact of acutely induced LV dyssynchrony on long-term survival of this specific subgroup of patients. The long-term survival of heart failure patients with and without induced LV dyssynchrony after CRT implantation was compared with the long-term survival of a group of patients with baseline LV dyssynchrony treated with CRT.

Methods

Patient population and data collection

Patients with New York Heart Association (NYHA) functional class III or IV heart failure symptoms despite optimal medical therapy, LVEF ≤ 35%, and QRS duration ≥ 120 ms were selected for CRT. Before CRT implantation, clinical status was evaluated and two-dimensional echocardiography was performed to measure LV volumes and LVEF. In addition, LV mechanical dyssynchrony was evaluated with tissue Doppler imaging (TDI). A total of 290 consecutive patients without significant LV mechanical dyssynchrony before CRT (LV dyssynchrony value at baseline < 60 ms) were selected from an ongoing registry. Patients with recent myocardial infarction (< 3 months) and decompensated heart failure requiring continuous intravenous therapy were excluded from the present analysis. Patient data were prospectively recorded in the departmental Cardiology Information System (EPD vision, Leiden University Medical Centre) and retrospectively analysed.

According to the clinical protocol, within 48 h after CRT implantation, the patients underwent repeat echocardiography to evaluate whether a significant change in LV mechanical dyssynchrony occurred. Subsequently, patients were divided into two groups according to the median value of LV dyssynchrony assessed at 48 h after CRT implantation. Patients with LV dyssynchrony equal or superior to the median value formed the induced LV dyssynchrony subgroup.

At 6-month follow-up, the clinical evaluation was repeated and LV volumes, LVEF, and LV dyssynchrony were reassessed. Response to CRT was defined by ≥ 15% reduction in LV end-systolic volume (LVESV) at 6-month follow-up.

Baseline characteristics, CRT response rate at 6-month follow-up, and long-term outcome of patients with induced LV dyssynchrony after CRT implantation were compared with patients without induced LV dyssynchrony.

In addition, a group of 290 patients with overt LV mechanical dysynchrony before CRT implantation (LV dyssynchrony value at baseline ≥ 60 ms) were selected from the ongoing registry. These patients formed the control group and were matched with the group of patients without baseline LV mechanical dyssynchrony according to age, gender, baseline LVEF, and NYHA functional class. The patients received CRT during the same time period as the group of patients without baseline LV dyssynchrony. The long-term survival of patients with and without significant induction of LV dyssynchrony at 48 h after CRT implantation was compared with the outcome of patients with overt LV dyssynchrony at baseline.

Clinical evaluation

Baseline clinical evaluation included the assessment of NYHA functional class, quality-of-life score (using the Minnesota Living with Heart Failure Questionnaire), and evaluation of exercise capacity using the 6 min walk distance test.

Echocardiography

Patients were imaged in the left lateral decubitus position using a commercially available system (Vingmed system Seven, General Electric-Vingmed, Milwaukee, WI, USA). Images were obtained using a 3.5 MHz transducer, at a depth of 16 cm in the parasternal and apical views (standard long-axis and two- and four-chamber images). Standard two-dimensional and colour Doppler data, triggered to the QRS complex, were saved in a cine-loop format.

The end-systolic and end-diastolic LV volumes and LVESV were measured from the conventional apical two- and four-chamber images, using the biplane Simpson’s technique. All echocardiographic data acquisitions and analyses were performed blinded to the patients’ baseline characteristics and clinical outcome. The intra-observer reproducibility for left ventricular end-diastolic volume (LVEDV), LVESV, and LVEF was 7.4 ± 11.2, 7.0 ± 10.1 mL, and 1.9 ± 4.4%, respectively. The inter-observer reproducibility for LVEDV, LVESV, and LVEF was 12.9 ± 14.7, 11.3 ± 13.9 mL, and 2.5 ± 4.9%, respectively.

Left ventricular mechanical dyssynchrony assessment

In addition to the conventional echocardiographic examination, colour-coded TDI was performed to assess LV dyssynchrony. For TDI data acquisition, colour Doppler frame rates were set between 80 and 220 frames/s; pulse repetition frequencies were between 500 Hz and 1 KHz, resulting in aliasing velocities between 16 and 32 cm/s. TDI parameters were measured off-line from colour-coded images of three consecutive heartbeats. Data were analysed using commercial software (EchoPac 108.1.5, General Electric-Vingmed Ultrasound).

To determine LV dyssynchrony, the sample volume (6 mm x 12 mm) was placed in the LV basal parts of the septal and lateral walls (four-chamber apical view) and the time interval between the onset of the QRS complex and the peak systolic velocity was derived for each region. Left ventricular dyssynchrony was defined as the maximum delay between peak systolic velocities of the septal and the lateral walls. The analysis of peak systolic velocities was limited to the LV ejection period and post-systolic peaks were not included. Previously reported inter- and intra-observer agreement for assessment of LV dyssynchrony with colour-coded TDI was 90 and 96%, respectively.

Pacemaker implantation

The LV pacing lead was inserted transvenously via the subclavian route. A coronary sinus venogram was obtained using a balloon catheter. Next, the LV pacing lead (Easytrak, Guidant Corporation, St Paul, MN, USA; Attain, Medtronic Inc., Minneapolis, MN, USA; or Corox, Biotronik, Berlin, Germany) was inserted through the coronary sinus with the help of an 8 Fr-guiding catheter and positioned in the venous system, preferably in a posterolateral vein. The right atrial and right ventricular leads were positioned conventionally. The CRT device and lead implantation were successful in all patients without major complications (Contak Renewal, Guidant Corporation; Insync III or Insync Sentry, Medtronic Inc.; or Lumax, Biotronik).
Within 24 h after CRT device implantation, the atioventricular delay was adjusted to optimize LV diastolic filling as assessed with pulsed-wave Doppler echocardiography. The interventricular delay was set at 0 ms and was not systematically adjusted during the first 6 months of follow-up.

**Outcome at long-term follow-up**

Long-term follow-up was performed by chart review and telephone contact. All-cause mortality was the primary endpoint. Data on mortality were collected by reviewing medical records and retrieval of survival status through the municipal civil registries. All clinical variables were collected by independent observers blinded to the echocardiographic results. The long-term survival was compared between the following three groups of patients:

- patients without significant LV dyssynchrony at baseline and after CRT implantation,
- patients without significant LV dyssynchrony at baseline but induced LV dyssynchrony at 48 h after CRT implantation, and
- patients with significant LV dyssynchrony at baseline.

**Statistical analysis**

Continuous data are expressed as mean ± SD or median and inter-quartile range, as appropriate, and were compared with the two-tailed Student’s t-test for paired and unpaired data or a non-parametric test (Mann–Whitney U-test) when appropriate. Categorical variables are expressed as number and frequencies and were compared using the χ² test. Changes in LV dyssynchrony along the three different time points of follow-up were compared with the Friedman test. Survival curves were determined according to the Kaplan–Meier method and comparisons of cumulative event rates were performed by the log-rank test. Cox’s proportional hazard analysis was used to determine the value of acute LV dyssynchrony induction to predict long-term survival. First, univariate analysis of baseline clinical and echocardiographic characteristics was performed using all-cause mortality as an endpoint. For each variable, the hazard ratio (HR) and the 95% confidence intervals (CI) were calculated. In the multivariate analysis, the predictive values of acute LV dyssynchrony were divided into two groups: patients with LV dyssynchrony (≥ 60 ms) at baseline and patients with LV dyssynchrony (< 60 ms) at baseline.

**Results**

**Patient population**

A total of 290 consecutive patients without baseline LV mechanical dyssynchrony (< 60 ms) and 290 patients with overt LV mechanical dyssynchrony (≥ 60 ms) at baseline were selected from an ongoing registry. Baseline characteristics of all patients are summarized in Table 1. The population comprised mostly men (77%), with a mean age of 67 ± 10 years. Heart failure was of ischaemic aetiology in 173 (59%) patients. The mean QRS duration was 152 ± 31 ms.

Continuous variables are expressed as mean ± SD. Left ventricular dyssynchrony is expressed as median and inter-quartile range. Categorical variables are expressed as n (%).

**Changes in left ventricular mechanical dyssynchrony after cardiac resynchronization therapy**

In patients without significant LV dyssynchrony at baseline, the median baseline LV dyssynchrony was 22 ms (inter-quartile range: 16–34 ms). After 48 h of continuous CRT, LV dyssynchrony increased to 40 ms (inter-quartile range: 24–56 ms) and remained unchanged at 6-month follow-up [40 ms (inter-quartile range: 24–67 ms)] (P < 0.001; Figure 1). Conversely, in the group of patients with significant LV dyssynchrony at baseline, the median LV dyssynchrony was 100 ms (inter-quartile range: 80–120 ms) and decreased to 45 ms (inter-quartile range: 20–70 ms) at 48 h and remained unchanged at 6-month follow-up [39 ms (inter-quartile range: 19–63 ms)] (P < 0.001).

**Cardiac resynchronization therapy response in patients without baseline left ventricular mechanical dyssynchrony**

According to the median value of LV dyssynchrony measured 48 h after CRT implantation, patients without significant baseline LV dyssynchrony were divided into two groups: patients with LV...
dyssynchrony $\geq 40$ ms and patients showing LV dyssynchrony <40 ms.

Baseline characteristics of these two groups are presented in Table 2. Patients with LV dyssynchrony $\geq 40$ ms were older (68 ± 9 vs. 65 ± 11 years, $P = 0.004$) and had more frequently ischaemic aetiology of heart failure (73 vs. 46%, $P < 0.001$) compared with patients with LV dyssynchrony <40 ms.

At 6-month follow-up, there were 81 patients (28%) who responded to CRT (defined by a decrease of $\geq 15\%$ in LVESV) and 209 patients (72%) who did not respond to CRT. A total of 40 patients showed an increase in LVESV $\geq 15\%$ at 6-month follow-up. The percentage of non-responders was significantly higher in the group of patients with LV dyssynchrony $\geq 40$ ms after 48 h of CRT compared with the group of patients with LV dyssynchrony <40 ms (93 vs. 51%, $P < 0.001$).

Long-term outcome of patients with vs. without induced left ventricular dyssynchrony

During a median follow-up of 34 months, a total of 73 (25.1%) patients without baseline LV dyssynchrony died. When the patient population was divided according to the median LV dyssynchrony assessed 48 h after CRT implantation ($<40$ vs. $\geq 40$ ms), a cumulative 10, 17, and 23% of patients with LV dyssynchrony $\geq 40$ ms died by 1-, 2-, and 3-year follow-up, respectively. In contrast, the group of patients with LV dyssynchrony <40 ms at 48 h after CRT implantation had superior outcome and, respectively, 3, 8, and 10% of patients died during the same time period (log-rank $P < 0.001$; Figure 2). Finally, in the group of patients with significant LV dyssynchrony at baseline, 57 (19.7%) patients died during follow-up. The cumulative mortality rate in this group of patients at 1-, 2-, and 3-year follow-up was 3, 8, and 11%, respectively.

Continuous variables are expressed as mean ± SD. Left ventricular dyssynchrony is expressed as median and inter-quartile range. Categorical variables are expressed as n (%). 6MWT, 6 min walk distance test; IVCD, unspecified intra-ventricular conduction delay; LBBB, left bundle branch block; LVEDV, left ventricle end-diastolic volume; LVEF, left ventricular ejection fraction; LVESV, left ventricle end-systolic volume; NYHA, New York Heart functional class; QoL, quality-of-life questionnaire (Minnesota living with Heart Failure); RBBB, right bundle branch block.
and compared favourably with the group of patients with LV dyssynchrony <40 ms at 48 h after CRT implantation (log-rank P = 0.375).

Among the patients without baseline LV dyssynchrony and who exhibited an increase in LVEF ≥15% at 6-month follow-up, a total of 13 patients died after a median follow-up of 34 months. In this group of patients, cumulative mortality rates at 1-, 2-, and 3-year follow-up were 5, 26, and 36%, respectively.

Baseline clinical and echocardiographic parameters were evaluated to predict all-cause mortality for patients without baseline LV dyssynchrony. In the univariate analysis, age, ischaemic aetiology of heart failure, NYHA functional class, LVEF, and acute LV dyssynchrony were significant predictors of all-cause mortality (Table 3). In the multivariate Cox regression analysis, induced LV dyssynchrony was an independent predictor of all-cause mortality with an HR of 1.247 for each 20 ms increase (95% CI: 1.056–1.474, P = 0.009). Age, ischaemic aetiology of heart failure, baseline NYHA functional class, and baseline LVEF were also significantly related to all-cause mortality (Table 3).

**Importance of assessing left ventricular dyssynchrony before cardiac resynchronization therapy implantation**

QRS complex width is presently used to select patients for CRT as a measure of LV dyssynchrony. However, electrical dyssynchrony is not equivalent to LV mechanical dyssynchrony and a poor correlation between QRS duration and LV dyssynchrony has been reported. Furthermore, heart failure patients with narrow QRS complex may show echocardiographic mechanical LV dyssynchrony amenable to be corrected with CRT.

The additional value of echocardiographic LV dyssynchrony assessment before CRT implantation has been demonstrated in many single-centre trials. The presence of baseline LV dyssynchrony predicts favourable response to CRT and improved long-term outcome. In addition, recent subanalysis of the PROSPECT trial, including 286 patients treated with CRT, demonstrated that larger baseline LV dyssynchrony as assessed with TDI was strongly associated with larger reduction in LVEF at 6-month follow-up (P = 0.0022). Furthermore, it has been suggested that the persistence of LV dyssynchrony after CRT may be a reason for suboptimal response at follow-up. Based on this evidence, CRT appears to exert beneficial effects in those patients with baseline LV dyssynchrony and induces a favourable LV reverse remodelling with improved outcome at mid- and long-term follow-up. However, the effects of CRT on LV dyssynchrony in patients without significant baseline LV mechanical dyssynchrony have not been extensively studied. In addition, it was unclear whether an eventually induced LV mechanical dyssynchrony after CRT may impact on long-term prognosis of heart failure patients. The present study

6MWT, 6 min walk distance test; LV, left ventricle; LVEF, left ventricle ejection fraction; LVEDV, left ventricle end-diastolic volume; LVESV, left ventricle end-systolic volume; NYHA, New York Heart functional class; QoL, quality-of-life questionnaire (Minnesota living with Heart Failure).
demonstrated for the first time that CRT may induce LV mechanical dyssynchrony which was associated with less favourable LV reverse remodelling and worse long-term prognosis.

**Effects of cardiac resynchronization therapy on left ventricular dyssynchrony**

In heart failure patients fulfilling the current inclusion criteria for CRT, the prevalence of LV mechanical dyssynchrony as assessed with TDI is around 69–75%. In this subgroup of patients, after CRT implantation, the majority of patients show a significant reduction in LV mechanical dyssynchrony which has been associated with favourable LV reverse remodelling. However, in 5% of patients with overt LV mechanical dyssynchrony at baseline, CRT may induce worsening of LV dyssynchrony and prevent LV reverse remodelling. In contrast, 25–31% of the patients who may eventually receive a CRT device do not show LV mechanical dyssynchrony at baseline. In this subgroup of patients, CRT may induce LV mechanical dyssynchrony, as demonstrated in the present study.

As previously mentioned, QRS duration is not the optimal criterion to identify the patients who will respond to CRT. In contrast, QRS morphology may provide further assessment of the pattern of activation within the LV. The results of a recent subanalysis of the MADIT-CRT trial have shown that the patients with left bundle branch block (LBBB) exhibit a greater clinical benefit from CRT compared with patients with other QRS complex morphologies (i.e. right bundle branch block or unspecified interventricular conduction delay). However, LBBB is a heterogeneous conduction disorder yielding different LV activation time delays as assessed by surface ECG. Indeed, despite a wide QRS complex with LBBB morphology, Sweeney et al. showed that patients with shorter LV activation time delays (≤80 ms) had a 51% response rate compared with 73% response in patients with larger LV activation time delays (≥125 ms). These differences in LV activation time delays may result in different LV mechanical activation patterns that determine a different response to CRT. Therefore, the presence of LV mechanical dyssynchrony amenable to be corrected with CRT rather than only the width or morphology of the QRS complex may be more important to predict a favourable response to CRT. In the present study, despite showing a QRS width of ≥120 ms, a substantial number of patients did not show LV mechanical dyssynchrony on TDI echocardiography. After CRT, a significant percentage of patients showed increased LV dyssynchrony which remained at 6-month follow-up. The group of patients with induced LV dyssynchrony after CRT showed a lower response rate and worse long-term outcome when compared with patients without induced LV dyssynchrony. In contrast, the control group formed by heart failure patients with overt LV mechanical dyssynchrony at baseline showed a significant decrease in LV mechanical dyssynchrony and improved long-term outcome. Several trials have demonstrated the relationship between restoration of LV synchrony and CRT response and improved long-term outcome. In contrast, the results of the present evaluation provide novel insights by demonstrating that the lack of response to CRT may be explained by induction of LV dyssynchrony in patients who show LV synchronous contraction despite wide QRS complex.

**Clinical implications**

Previous studies have shown the long-term benefits of CRT implantation in advanced heart failure patients. CRT induces LV reverse remodelling and improves survival by restoring LV synchrony. However, in a significant percentage of patients without LV dyssynchrony at baseline, CRT induced LV dyssynchrony acutely. This group of patients had worse outcome than patients without induced LV dyssynchrony. Therefore, in a patient selection process for CRT, accurate assessment of LV mechanical dyssynchrony seems to be clinically relevant, since the induction of LV dyssynchrony after CRT may prevent LV reverse remodelling and portend worse long-term outcome. In addition, close monitoring of LV mechanical dyssynchrony after CRT implantation and further adjustments of the device settings, such as interventricular delay, to correct LV dyssynchrony may help to increase the favourable response rate to CRT and to improve long-term survival.

Several limitations have to be acknowledged. First, the present evaluation is a retrospective analysis and, accordingly, we cannot conclude whether withdrawal of CRT should be indicated in patients who show worsening of LV dyssynchrony after CRT. A post hoc analysis from the MADIT-CRT trial has recently demonstrated that LV mechanical dyssynchrony worsening was associated with an increased risk for the occurrence of primary endpoint (death or heart failure event). Despite the study was not primarily designed to demonstrate the relationship between changes in LV synchrony and outcomes, the data come from one of the largest series of patients included in a randomized controlled trial and are in line with the results of the current evaluation. However, these data should be interpreted with caution and additional randomized controlled trials are needed to confirm this hypothesis. Secondly, the assessment of LV dyssynchrony was performed only with TDI. Reproducibility was one of the main limitations of this technique in the PROSPECT trial. However, in high experienced centres, the reproducibility of TDI-derived LV dyssynchrony is good. The results of the PROSPECT trial promoted the research of novel LV dyssynchrony measurements that are currently tested in randomized control trials including heart failure patients who fulfil (TARGET trial) and do not fulfil the current inclusion criteria for CRT (i.e. EchoCRT trial). The use of radial strain imaging with speckle tracking, for example, may be more appropriate since it overcomes some of the limitations of TDI (angle insonation dependency, tethering and traction from other myocardial regions, and cardiac translational artefacts) (see supplementary material). Finally, the baseline characteristics of patients with and without induced LV dyssynchrony were not completely comparable. The group of patients with induced LV dyssynchrony after CRT had more frequently ischaemic heart failure and poorer exercise capacity compared with patients without induced LV dyssynchrony.

**Conclusion**

In heart failure patients without LV mechanical dyssynchrony at baseline, induction of LV dyssynchrony after CRT may be associated with a less favourable response rate and less favourable long-term outcome. Therefore, LV mechanical dyssynchrony
assessment at baseline in heart failure patients undergoing CRT implantation could be crucial in order to anticipate the results of the therapy. The absence of LV mechanical dyssynchrony at baseline may anticipate the need for further adjustments of the device settings in order to minimize the induction of LV dyssynchrony after CRT implantation.
