The genome sequence and transcriptome of Potentilla micrantha and their comparison to Fragaria vesca (the woodland strawberry)

Abstract:
Background: The genus Potentilla is closely related to that of Fragaria, which contains the economically important cultivated strawberry F. × ananassa. Potentilla micrantha is a species that does not develop berries, but shares numerous morphological and ecological characteristics with F. vesca. These similarities make P. micrantha an attractive choice for comparative genomics and expression studies with F. vesca. In this study, the Potentilla micrantha genome was sequenced and annotated, and RNA-Seq data from the different developmental stages of flower and fruit of these two species were compared.

Results: Here we present a 327 Mbp sequence and annotation of the genome of Potentilla micrantha, spanning 2,674 sequence contigs, with an N50 size of 335,712. The sequence is estimated to cover 80% of the estimated total genome size of the species determined through flow cytometry. We show that the genus Potentilla has a characteristically larger genome size than Fragaria. The recovered sequence scaffolds were remarkably collinear at the micro-syntenic level with the genome of F. vesca, its closest sequenced relative, however no macro-syntenic comparisons were possible using the presented data. A total of 33,602 genes were predicted, and 95.1% of BUSCO genes were complete within the presented sequence. Thus, we argue that the majority, if not all of the gene-rich regions of the genome have been sequenced.

Comparisons of RNA-Seq data from the stages of floral and fruit development revealed genes differentially expressed between P. micrantha and F. vesca during fruit development.

Conclusions: The new genome and transcriptome data are a valuable resource for future studies of fleshy berry development in Fragaria and fruit formation in the Rosaceae family. New data also shed light on the evolution of genome size and organization in this family.
Dear Editor,

Please find attached the revision of our original article. Below please find a point-by-point description of the changes made in the light of the reviewers' comments. We would like to thank both you and the reviewers, as we feel the changes that have been made have significantly enhanced and strengthened the paper.

Reviewer 1
We have toned down the whole of the manuscript to reflect the descriptive nature of our data and have likewise changed the title of the paper to: The genome sequence and transcriptome of Potentilla micrantha and their comparison to Fragaria vesca (the woodland strawberry).

The figure legends have been checked and corrected where necessary.

The figure relating to anchoring of scaffolds has been moved to the supplementary material and replaced with figures relating to synteny of specific scaffolds rather than the genome as a whole. Additionally, we have ensured throughout the text that it is clear that only micro-synteny was evaluated.

A BUSCO analysis has been performed and presented.

An analysis showing the overlap between the DEGs in each species was performed, as well as a visualisation of the genes from each species and the GO class they fall into.

The Transposon analysis section has been reduced.

The hormonal treatment analysis has been removed from the paper.

The miR1511 data has been removed from the paper as further work would have been required to strengthen this section sufficiently for publication which was not possible since almost all authors now no longer work at FEM where this work was initiated.

Reviewer 2
We appreciate the comments regarding the mechanisms of differentiation, and indeed at the inception of the project this was to be a major focus of the work; however, we were not able to progress in this area sufficiently to make this a major part of the manuscript. We hope that other groups will be able to study this area, building on the work we present here.

We have added a space between x and ananassa.

We have removed the redundancy and made clearer the objectives of the study.

Figure numbering has been corrected.
The ML study is presented the others have been referred to as data not shown. Plants were selected from Serbia as we had a collaborator there who guided us to a large population from which we could sample plant material easily. Redundancy has been removed from the HiSeq2000 methods section. We have adjusted the text relating to FPKM to clarify that highly expressed genes were those with FPKM >1000 and on/off genes were those where no expression data were observed. A space was added to sqrt (MSR). Abbreviations have been added for ML, MP and NJ in the text. Resolution of the figures has been improved and font size increased to improve clarity. Figure legends for the phylogenetic analysis have been improved. The text resolution on the submitted figures is much better than in the reviewer copy. We hope that in the revised version, the reviewers have access to higher resolution images where text is hopefully clear and legible.

Reviewer 3
The text has been modified throughout to make clearer that only micro-synteny was evaluated. Likewise, the figures relating to this section have been changed to reflect and emphasise the micro-synteny. The abundance of GO terms for the DEGs in each species has been highlighted through an additional figure, and those classes that were in greater abundance are identified. Likewise, a heatmap of the expression levels of genes shared between the two species has been produced and those that differ in their expression patterns have been identified. The title and text have been toned down to reflect the results presented more accurately.

We look forward to hearing from you in due course regarding this resubmission, Best regards,
Dan Sargent (on behalf of all authors).

ABSTRACT

Background: The genus Potentilla is closely related to that of Fragaria, which contains the economically important cultivated strawberry F. × ananassa. Potentilla micrantha is a species that does not develop berries, but shares numerous morphological and ecological characteristics with F. vesca. These similarities make P. micrantha an attractive choice for comparative genomics and expression studies with F. vesca. In this study, the Potentilla micrantha genome was sequenced and annotated, and RNA-Seq data from the different developmental stages of flower and fruit of these two species were compared.

Results: Here we present a 327 Mbp sequence and annotation of the genome of Potentilla micrantha, spanning 2,674 sequence contigs, with an N50 size of 335,712. The sequence is estimated to cover 80% of the estimated total genome size of the species determined through flow cytometry. We show that the genus Potentilla has a characteristically larger genome size than Fragaria. The recovered sequence scaffolds were remarkably collinear at the micro-syntenic level with the genome of F. vesca, its closest sequenced relative, however no macro-syntenic comparisons were possible using the presented data. A total of 33,602 genes were predicted, and 95.1% of BUSCO genes were complete within the presented sequence. Thus, we argue that the majority, if not all of the gene-rich regions of the genome have been sequenced. Comparisons of RNA-Seq data from the stages of floral and fruit development revealed genes differentially expressed between P. micrantha and F. vesca during fruit development.

Conclusions: The new genome and transcriptome data are a valuable resource for future studies of fleshy berry development in Fragaria and fruit formation in the Rosaceae family. New data also shed light on the evolution of genome size and organization in this family.
Keywords: long-read sequencing; evolutionary development; angiosperms; genome sequence; transcriptomics;

BACKGROUND

Potentilla, a genus of approximately 500 species [1], is closely-related to that of Fragaria [2], the genera having diverged from a common ancestor just 24 million years ago [3]. The genus Fragaria, a member of the Fragariiinae tribe of the Rosaceae family, is economically-important due to the sweet, aromatic accessory fruits (berries) produced by members of the genus, in particular those of the cultivated allo-octoploid (2n=8×=56) strawberry species F. × ananassa. A significant research effort was invested into improvements in yield and fruit quality of the berries of the cultivated strawberry, the focus of which has included the physiological, metabolic, and genomic changes taking place during berry development and ripening [4–8]. In addition, numerous resources have been developed to assist both applied and basic research, including a genome sequence for the wild diploid relative of the cultivated strawberry, the woodland strawberry F. vesca (2n=2×=14) [9]. The availability of this genomic sequence facilitated further investigation of the molecular basis of many traits of economic and academic interest, including the development of accessory fruits. However, all members of the Fragaria genus produce berries, and as such the use of reverse genetics approaches to study the genes involved in berry evolution and development would require Fragaria mutants that do not produce fruits, a resource that is not currently available.

In the post genomics era comparative analysis permits the study of related, yet divergent species, by tracing changes at the genomic and transcriptomic levels responsible for their phenotypic differences. Previously, the sequenced genomes of F. vesca, Prunus persica and Malus × domestica were compared [10]; the study revealed insights into the evolutionary mechanisms that have shaped the three species, demonstrating that the Fragaria genome underwent significant small-scale structural rearrangement since it diverged from the common ancestor of the three genera. Comparisons of global
gene expression between species, such as one performed between wild and cultivated tomato species [11], can reveal patterns of selection that have led to domestication, or to differences in gene expression in response to environmental conditions, such as cold stress in banana and plantain [12]. Comparative transcriptomics can also be used to reveal differences in the expression of orthologous genes between organisms at different stages of physiological development [13]. Such an approach suggests that comparative analyses between *Fragaria* and a closely-related species that does not bear berries may reveal important insights into the evolution of fruit development. Additionally, species separation is often related to changes in genome structure, and genome size in particular. Differences in genome size are often the consequence of polyploidization events and/or changes in the abundance of repetitive DNA, especially transposable elements [14].

The *Potentilla* genus contains a single species (*P. indica*) that produces accessory fruits, or berries, similar in size and appearance to those of the genus *Fragaria*. However, the polyphyly of *Fragaria* and *Potentilla* demonstrates that the berry-bearing habit evolved independently in the Fragariinae on a number of occasions [2], and that its evolution might therefore involve relatively simple genomic mechanisms.

*Potentilla micrantha*, like the majority of species within the genus does not develop accessory fruits, but shares numerous morphological characteristics with *F. vesca* (Fig. 1) including plant habit and flower morphology. Notably, they grow within the same ecological niches, and where their ranges of distribution overlap, *P. micrantha* can be found growing nearby populations of *F. vesca* (Sargent, unpublished results). These striking similarities make *P. micrantha* an attractive choice for comparative genomics studies with *F. vesca* to study the genetic basis of berry development in the latter species. As a precursor to a whole genome sequencing initiative, an initial sequencing project focused on the *P. micrantha* chloroplast was undertaken using the Illumina HiSeq and PacBio RS sequencing platforms [15].

The objectives of this study were to develop a genomic toolkit for *P. micrantha* to permit comparative genomic and transcriptomic studies with *F. vesca*, with a view to identifying the evolutionary changes
that have occurred between the two species. The genome size of *P. micrantha* was determined and the nuclear genome was sequenced and assembled from Illumina and PacBio sequencing reads. Gene predictions from the *P. micrantha* genome were made with support of RNA-Seq data generated from tissue libraries sampled during flower and fruit development. The genome of *F. vesca* was compared to the sequencing scaffolds produced for *P. micrantha*, and whilst they exhibited a remarkable degree of collinearity at the micro-syntenic level, large-scale differences in transposon activity were identified that could be responsible for the large differences in genome size between the two species.

**RESULTS**

**Flow cytometry, heterozygosity estimation and genome assembly**

DNA was extracted from *Potentilla micrantha* young, unexpanded leaves. Flow cytometry using a *V. minor* internal standard with a DNA content of 1.52 pg/2C returned average DNA quantities of 0.52 pg/2C for *F. vesca* ‘Hawaii 4’ and 0.83 pg/2C for *P. micrantha* over three biological replicates. Using the calculation of Dolezel et al. (2003) [16] that 1 pg DNA is equivalent to 978 Mbp of DNA sequence, the genome size of *P. micrantha* was determined as 405.87 Mbp in length whilst that of *F. vesca* ‘Hawaii 4’ was calculated to be 254.28 Mbp.

Data were returned for the overlapping fragment library (OLF) and all four mate-pair libraries sequenced using Illumina HiSeq. In total, 61.4 Gbp of data were returned and the relative depth of coverage obtained for the *P. micrantha* genome from each library is given in Additional File 1: Table S1. Four different PacBio RS sequencing libraries were constructed and sequenced using two different versions of the PacBio chemistry (Additional File 2: Table S2). From the sequencing of 63 SMRT cells, 6,447,413 sequences with an average length of 2,221 bp were recovered, totaling 14.32 Gb of long read sequence data. From the data, 33× equivalent of sequence was contained in reads longer than 1 kb which were used for gap filling of the Illumina assembly using PBJelly [17].
The initial ALLPATHS assembly of the Illumina short-read sequences produced 33,026 contigs with an N50 of 16,235 bp and a total length of 247,565,733 bp. Following scaffolding, a genome assembly with a total length of 315,266,043 bp contained in 2,866 sequencing scaffolds was returned. The final scaffold set returned following ALLPATHS assembly contained a total of 0.07% ambiguous sites (SNPs), revealing the genome of *P. micrantha* to be one of the most homozygous naturally-occurring genomes sequenced to date. Following incorporation of the PacBio RS data using PBJelly [17], the *P. micrantha* sequence assembly contained 326,533,584 bp of sequence data, a 3.5% increase over the ALLPATHS Illumina assembly, in 2,674 scaffolds. The longest and N50 scaffold lengths both increased following gap filling by 9.3% and 5.1% respectively, but most significantly, the number of gapped Ns in the assembly was reduced by 59.7% to 27,311,787 (8.4% of the final assembly) (Table 1). The final scaffolded assembly contained 80.45% of the total estimated genome size for *P. micrantha* as calculated by flow cytometry. Sequence scaffold size ranged from 935 bp to 3,488,351 bp. Of the 2,674 scaffolds, 878 (32.8%) were less than 10 kbp in length, 534 (20%) were between 10 and 50 kbp in length, 738 (27.6%) were between 50 and 200 kbp in length, 500 (18.7%) contained between 200 kbp and 1 Mbp of sequence, and the remaining 23 (0.9%) contained over 1 Mbp of sequence. The majority of the 1,440 benchmarking single-copy orthologous (BUSCO) groups queried [18] were present in the genome sequence, with 95.1% (1,337 complete and single copy and 33 complete and duplicated BUSCOs) identified within the sequencing scaffolds.

**Gene prediction and preliminary annotation**

The results of the combined alignment of the 12 RNA-seq read sets to the *Potentilla* genome sequence scaffolds and number of splice sites identified using STAR is presented in Additional File 3: Table S3. A total of 1,908 consensus repeat sequences were generated by RepeatModeler totaling 1,431,262 bp and having a GC content of 40.8%. The total ATCG content of sequencing scaffolds greater than 10 kb in length was 298,987,576 bp. A total of 138,597,969 bp (46.36%) of the genome sequence were masked using the consensus sequences in the RepeatModeler library, including 26,359
(7.5%) of the mapped GT-AG introns identified by STAR. Gene prediction using GeneMark-ET on the masked genome identified a total of 33,602 genes, of which 32,137 were predictions containing multiple exons, and 4,655 were single exon predictions. A total of 172,791 exons were predicted, with an average length of 223 bp and an average of 5.14 exons per gene. A total of 139,216 introns were predicted in the CDs of the genes, with an average intron length of 499 bp. In total 88.9% of the 1,440 BUSCO groups queried were identified in the gene predictions. Following a local BLAST search and BLAST2GO analysis, a total of 27,968 genes were assigned a preliminary gene annotation.

**Scaffold anchoring and synteny to the Fragaria vesca Fvb genome sequence**

Following BLAST analysis, a total of 24,641 *P. micrantha* genes returned significant hits to the *F. vesca* v2.0 pseudomolecules using the criteria set out in the Materials and Methods. A total of 1,682 *P. micrantha* sequence scaffolds, containing 315,081,089 bp (96.5% of the total sequence) contained at least one gene that was anchored to one of the *F. vesca* v2.0 pseudomolecules. Of those, 573 contained at least ten orthologous gene sequences, 118 contained at least 50 orthologous sequences and 32 contained over 100 orthologous (Supplementary Excel File 1). Scaffold ‘Contig145’, the largest scaffold in the *P. micrantha* genome sequence (3,488,351 bp) contained the largest number of orthologous gene sequences anchored to the *F. vesca* v2.0 genome sequence (560), whilst scaffold ‘Contig2191’ was the smallest anchored scaffold at 1,163 bp, and containing a single orthologous gene sequence. Comparison of the two genomes revealed a remarkable degree of micro-synteny with majority of the *P. micrantha* scaffolds spanning uninterrupted regions of the *F. vesca* genome sequence (Additional File 4: Fig. S1). A very high degree of collinearity in gene order was observed between *P. micrantha* scaffolds and the *F. vesca* pseudomolecules (Fig. 2a). In general, only a small number of inversions were observed between syntenic blocks between the two genomes, and very few *Potentilla* scaffolds aligned with more than one *Fragaria* pseudomolecule (Fig. 2b). Scaffold anchoring to a genetic map however was not performed for the *P. micrantha* genome sequence, and as such, a comparison of macrosynteny between *Fragaria* and *Potentilla* could not be made.
Gene expression during fruit development

Tissues from five stages of flowering and ‘fruit’ development were harvested from *Potentilla micrantha* untreated flowers in biological duplicates or triplicates for RNA isolation. The stages of flowering followed those identified in *Fragaria* by Kang et al. (2013) [8], with the addition of a stage 0 (unopened flowers) and young unexpanded leaf tissue. The selected developmental stages are shown in Fig. 3. RNA-libraries were made and sequenced with Illumina HiSeq2000. Following QC and adapters trimming, a total of 619,085,115 101 bp paired reads were obtained from the 12 *P. micrantha* RNA-seq libraries. Sequencing yield from individual libraries ranged from 29,653,058 to 60,158,302 reads per sample (Additional File 5: Table S4). Following trimming, the number of reads available for *Fragaria* from the published sequences of Kang et al. (2013) [8] were 1,236,882,540, with reads per library ranging from 109,643,225 to 155,643,061. Between 62% and 69% of *P. micrantha* filtered reads per library mapped to the *P. micrantha* gene prediction set, whilst similarly 63% to 67% of *F. vesca* filtered reads per library mapped to the *F. vesca* gene prediction set (Additional File 2: Table S4). A total of 1,556 genes were differentially expressed between the four developmental stages in at least one pair-wise comparison of the different stages in *P. micrantha*, whilst 816 genes were differentially expressed in *F. vesca* between the four stages (Fig. 4). A total of 52.44% and 43.38% of the differentially expressed genes were GO-annotated for *P. micrantha* and *F. vesca* respectively (Additional File 6: Fig. S2 [OLD FIG S1]). Analysis of the GO terms for *F. vesca* and *P. micrantha* revealed an enrichment for genes associated with lipid metabolic processes, transporter activity, and transcription factor activity and transcription regulator activity in *F. vesca* over *P. micrantha* (Fig. 5). The gene expression profiles between the four developmental stages studied in the two species showed no clear consistent patterns between the two species overall (Additional File 7: Fig. S3), however the common differentially expressed genes displayed largely similar expression patterns (Fig. 6), with some exceptions, most notably gene1369-v1.0-hybrid and its homologue in *P. micrantha* (17717_t), a predicted 3-hydroxy-3-methylglutaryl coenzyme A
reductase 1, which was highly expressed in *F. vesca* but exhibited far lower levels of gene expression in *P. micrantha*.

**Analysis of MADs-box conserved domain-containing genes in *Potentilla* and *Fragaria***

A total of 75 *P. micrantha* and 81 *F. vesca* predicted proteins containing MADs-box conserved domains were aligned and phylogenetic trees were constructed to reliably identify orthology relationships between *P. micrantha* and *F. vesca* genes. The three methods employed for phylogenetic reconstruction (ML, MP, NJ) returned largely congruent topologies for the nodes with more than 50% bootstrap support, with NJ providing a slightly more resolved tree given the use of a pairwise, instead of a partial deletion approach. Fig. 7 displays the ML phylogenetic reconstruction of the *P. micrantha* and *F. vesca* genes containing MADs-box, along with the gene expression levels for each gene (data for the NJ and MP trees are not shown). The majority of the genes were retained after the divergence of the species, indicated by a large proportion of orthologous pairs retrieved. Only a few events of lineage-specific gene loss/duplication were observed. Both observations are in line with the lack of ploidy changes within *P. micrantha* and *F. vesca* in the estimated 24.22 million years since species divergence. As expected, the majority of orthologous pairs shared similar expression patterns. Based on the ML gene tree however, three clades of orthologous genes were identified that were not expressed, or poorly expressed in *P. micrantha* but highly expressed in *F. vesca* (Fig. 8). The three clades, numbered as 1, 2 and 3 on Fig. 8, contained the following genes: clade 1 contained genes 27280_t (*P. micrantha*) and gene25871-v1.0-hybrid (*F. vesca*), which displayed highest homology to *A. thaliana* AGL36, a sequence-specific DNA binding transcription factor active during endosperm development [19]; clade 2 contained genes 26598_t (*P. micrantha*) and gene18483-v1.0-hybrid (*F. vesca*), whose closest *A. thaliana* homologue was AGL62, a MADS gene that promotes embryo development, indicating an essential role of endosperm cellularization for viable seed formation [20]; and clade 3 contained *P. micrantha* genes 23638_t, 23641_t and 759_t and *F. vesca* genes gene32155-v1.0-hybrid and gene13277-v1.0-hybrid, whose closest *A. thaliana* homologue AGL15 delays
senescence programs in perianth organs and developing fruits and alters the process of seed desiccation [21].

Analysis of the repetitive component of the Potentilla micrantha genome

In total, 1,001,838 of 1,484,780 reads clustered with RepeatExplorer were grouped into 107,190 clusters, representing 67.5% of the genome. No predominant repeat families were identified in the *P. micrantha* genome, with the most redundant repeat cluster representing just 1.18% of the total genome length. LTR-retrotransposons made up the main fraction (24.1%) of the *P. micrantha* genome (Fig. 9), with a Gypsy to Copia ratio of approximately 2:1. Terminal-repeat retrotransposons in miniature (TRIMs) were poorly represented, making up just 0.2% of the genome, whilst putative DNA transposons accounted for 5.7% of the genome and included putative CACTA, Harbinger, and hAT elements, with other, unclassified repeats accounting for 10.6% of the genome. A comparison of the repetitive portion of the *F. vesca* and *P. micrantha* genomes performed by pairwise clustering of Illumina sequence reads revealed significant diversification between the repetitive component of the genomes of the two species (Additional File 8: Fig. S4). Among the top 291 repeat clusters that had a genome proportion >0.01%, 107 were specific to *P. micrantha*, 51 were specific to *F. vesca*, whilst only 25 were similarly represented in the two species. Among all repeat classes, only ribosomal DNAs show similar genome proportions between *P. micrantha* and *F. vesca*.

Potentilla full-length LTR-RE characterization, annotation and insertion age

Of the 505 LTR-REs characterised, 220 (43.6%) belonged to the Copia superfamily, with the greatest proportion belonging to the Bianca family, 256 (50.7%) belonged to the Gypsy superfamily, with the greatest proportion belonging to the Ogre/TAT family, whilst the remaining 29 (5.7%) could not be placed into a specific superfamily. Table 2 lists the proportion of the annotated 505 LTR-REs in each superfamily, and the numbers of elements contained in each sub-family within the Copia and Gypsy super-families. For RE insertion age determination, the mean synonymous substitution rate between
*P. micrantha* and *F. vesca*, was estimated by comparing 50 orthologous genes, which equated to 52,703 bp of aligned sequences between the two species, resulting to be 0.064 synonymous substitutions per site (K\(_s\)). Using a timescale of 24.22 million years since the separation of *P. micrantha* and *F. vesca*, and a K\(_s\) of 0.064, the resulting synonymous substitution rate was 2.64×10\(^{-9}\) substitutions per year. As mutation rates for LTR retrotransposons have been estimated to be approximately two-fold higher than silent site mutation rates for protein coding genes (SanMiguel and Bennetzen 1998; Ma and Bennetzen 2004), a substitution rate per year of 5.28×10\(^{-9}\) was used in calculations of LTR-RE insertion dates. When the whole set of usable retrotransposons was taken into account, the nucleotide distance (K) between sister LTRs showed a large degree of variation between retro-elements, ranging from 0 to 0.124 using the Kimura two parameter method, which represents a time span of at most 23.54 million years.

**DISCUSSION**

In this investigation, we present a set of resources for *P. micrantha*, which will form the foundation for future genomics studies in the species. Here, the genome of *P. micrantha*, a member of the Rosaceae, a diverse family of fruiting perennial plant genera, was sequenced using both short-read Illumina and long-read PacBio sequence data, and the resulting data was assembled into a highly contiguous reference sequence for the genus *Potentilla*. The genome was shown here to be one of the most homozygous plant genomes sequenced to date, more homozygous than that of the fourth generation inbred line of *F. vesca* ‘Hawaii 4’ used to produce the reference sequence for *Fragaria* [9] and that of the predominantly selfing *R. occidentalis* [22], the two closest sequenced relatives of *P. micrantha*. PacBio data (using early iterations of the sequencing chemistry) were proficiently integrated with short-reads, significantly improving the contiguity of the assembly; however the PacBio throughput was not sufficient to permit independent *de novo* assembly. Nonetheless, whilst fragmented, the genome and sequence presented here have a quality similar to the *F. vesca* genome, containing significantly fewer un-sequenced gaps within scaffolds, and is far more contiguous than
that of *R. occidentalis* [22]. Along with the set of gene predictions presented, it represents a valuable resource for studying the genetic basis of a number of key morphological traits that differ between *P. micrantha* and its closest sequenced relatives.

*Potentilla* has been shown previously to be the genus most closely related to *Fragaria* [2], with some authors advocating for the inclusion of *Fragaria* within the *Potentilla* genus [23]. Despite their closeness, we show in this work that the genome of *P. micrantha* is 59.6% larger than that of *F. vesca*, and it is also larger than the available genomes of the other Fragariianae i.e. *Rubus* [24,25] and *Rosa* species [26,27]. *Potentilla* and *Fragaria* are separated by just 24.22 million years of evolution [3] and this investigation demonstrated that *P. micrantha* and *F. vesca* exhibit a remarkable degree of microsynteny of the coding portion of the genome, with the main differences being short-range inversions. Nonetheless, the apparent differences in insertion age of transposable elements in the two genomes has led to significant differences in the repetitive portions. Whereas the genome structure of *P. micrantha* is similar to that of most angiosperm species [28], with a repetitive component amounting to around 41.5% of the total genome content, the genome of *F. vesca* has been previously demonstrated to contain just 22% repetitive elements [9].

Contrary to the coding or non-repetitive genome, the repetitive fractions of the *P. micrantha* and *F. vesca* genomes are highly diversified, suggesting that the overwhelming majority of retrotransposon activity in the genus *Potentilla* occurred after the divergence of the two genera from their common progenitor. Recent sequencing and analysis of the *F. iinumae* genome [29] has shown that members of *Fragaria* share largely similar genome sizes at the diploid level and the flow cytometry data presented here suggests likewise that *Potentilla* species have genomes that are significantly larger with respect to *Fragaria* spp. As such, the data presented here strongly indicate that retrotransposon activity (or the lack thereof in the genus *Fragaria*) is responsible for the significant difference between the genome size of *Fragaria* and its closest relatives, and support the assemtation of Potter et al. (2007) [2] that *Fragaria* should be treated as a distinct genus, separate from *Potentilla*. 
Gene expression patterns for differentially expressed genes that were common to both *F. vesca* and *P. micrantha* were largely similar between the two species, however one gene, a 3-hydroxy-3-methylglutaryl coenzyme A reductase 1 homologue displayed significantly higher gene expression levels in *F. vesca*. The 3-hydroxy-3-methylglutaryl coenzyme A reductase 1 gene catalyzes the first committed step in the cytosolic isoprenoid biosynthesis pathway [30]. Loss of function mutants of this gene in *Arabidopsis* display a dwarf phenotype due to suppression of cell elongation and reduced sterol levels [30]. Sterols are precursors in cellulose synthesis, important for cell-wall formation [31] and fruit development, and as such, up-regulation in the 3-hydroxy-3-methylglutaryl coenzyme A reductase 1 gene during fruit development in *F. vesca* over *P. micrantha* may indicate a role for this enzyme in berry formation in *Fragaria*.

In contrast to the gene expression patterns of differentially expressed genes common to both *F. vesca* and *P. micrantha* during fruit development, global patterns of gene expression during fruit development differed between the two species. The gene ontology for the *F. vesca* expression profile was enriched for genes with transcription factor and transcription regulator activity as well as transporter activity and lipid metabolic processes. A study of the differences in transcriptional regulation between *F. vesca* and *P. micrantha* therefore may provide clues to the genetic basis of berry formation in *F. vesca*. MADS-box transcription factors have been implicated in a wide and extremely diverse array of developmental processes in plants [32], and were initially demonstrated to play a major role in floral organ differentiation, including gametophyte, embryo and seed development, as well as flower and fruit development. A study of the differential expression of MADS-box genes revealed three clades of orthologous genes where gene expression of orthologous genes was up-regulated in *F. vesca* with respect to *P. micrantha*. One clade contained genes that were homologous to AGL36, a transcription factor crucial for endosperm differentiation and development [19,33]. Another clade contained genes homologous to *A. thaliana* AGL62, which likewise has been implicated in embryo development, and is thought to have an essential role of endosperm cellularization for viable seed formation [20]. The third clade contained genes homologous to AGL15...
reported to have diverse roles in embryogenesis, fruit maturation, seed desiccation and the repression of floral transition [21,34], as well as being a positive regulator of the expression of mir156, a repressor of floral transition [35].

The set of genomics tools developed here for a non-fruiting relative of F. vesca, including a genome sequence, gene predictions and RNA-Seq data is a valuable foundational resource for more detailed future functional studies of fleshy receptacle or berry development.

METHODS

Plant material, flow cytometry and DNA isolation

A specimen of Potentilla micrantha was collected from Avala, Serbia in spring 2012 and subsequently used for sequencing. The plant was maintained in a growth room at a constant temperature of 24 degrees during the day and 18 degrees at night, with a 16-hour photoperiod to encourage new shoot development. Young leaves were harvested and subjected to flow cytometry by Plant Cytometry Services, NL. Measurements were taken in triplicate against a Vicia minor internal standard using the propidium iodide fluorescent dye. The F. vesca accession ‘Hawaii 4’ for which a whole genome sequence has been published [9] was analyzed for comparison. Prior to harvesting leaf material for DNA extraction, the plant was moved to a darkened growth chamber for 120 hours, maintaining a constant temperature of 22 degrees. DNA was extracted from young, unexpanded leaf material using the modified CTAB extraction protocol of Chen and Ronald (1999) [36], quantified using a Nanodrop spectrophotometer and Qubit fluorometer, and assessed for integrity by agarose gel electrophoresis against a λ HindIII size standard.

Since P. micrantha does not reproduce asexually from runners, a seedling population obtained from the selfing of the original mother plant was maintained from which to harvest tissue from stages of floral and fruiting development. Flowers of P. micrantha and F. vesca, along with two other Potentilla species, P. reptans and P. indica were treated with naphthaleneacetic acid (NAA; Sigma-Aldrich), N-1-naphthylphthalamic acid (NPA; Sigma-Aldrich), gibberellic acid (GA3; Sigma-
Aldrich) and a combination of NAA and NPA, following the methods of Kang et al. (2013) [8]. Briefly, stock solutions of 50 mM NAA, 50mM NPA, and 100mM GA3 were made in ethanol and diluted with two drops of Tween 20 and water before application. The final treatment concentrations were 500 μM for NAA and GA3 and 100 μM for NPA. 50 ml of hormone solution was pipetted onto the receptacle of each emasculated flower every two days for twelve days.

**Tissue sampling, RNA extraction and sequencing**

Tissues from five stages of flowering and ‘fruit’ development were harvested from untreated flowers in biological duplicates or triplicates for RNA isolation. The stages of flowering followed those identified in *Fragaria* by Kang et al. (2013) [8], with the addition of a stage 0 (unopened flowers) and young unexpanded leaf tissue. The selected developmental stages are shown in Fig. 3. RNA was extracted from 50 mg of snap-frozen tissue from each developmental stage using the Spectrum plant total RNA extraction kit (Sigma) with an on-column DNase I digestion (Sigma) step. The extraction protocol followed the manufacturers’ recommendations with two minor modifications: 1% PVP was added to the lysis solution, and the number of washes at each stage was doubled (i.e. two washes were performed with wash solution 1 and four washes were performed with wash solution 2). The RNA extracted from each sample was diluted in 50 μl of elution solution (Sigma). Following elution, total RNA was quantified using a Nanodrop spectrophotometer and Qubit fluorometer and assessed for integrity using a Bioanalyzer (Agilent). Samples returning a RIN value greater than 7.5 were considered acceptable for sequencing. A total of 12 Illumina TruSeq libraries were constructed from 2 μg of total RNA. Libraries were made from the following samples; one from stage 0, two from stage 1, two from stage 2, three from stage 3 and three from stage 4. A final library was made from RNA of young leaf tissue. The libraries were sequenced in triplex per single lane of Illumina HiSeq2000. Samples were indexed and multiplexed, and then 101 bp paired-end sequencing was performed using the Illumina HiSeq 2000 platform at the Weill Medical core genomics facility of Cornell University.
Whole genome shotgun sequencing, assembly

A strategy following the ALLPATHs-LG protocol was followed to produce an initial assembly using second-generation sequence data. Five sequencing libraries were developed; an overlapping fragment library (OLF) with an insert size of 170 bp, and four libraries of 3 kb, 5 kb, 8 kb and 12 kb. The OLF library was created using the Illumina Nextera library preparation kit following the manufacturers’ recommendations and was sequenced in simplex on a single lane of Illumina HiSeq2000, whilst the MP libraries were prepared using the Illumina Mate Pair Library v2 kit following the manufacturers’ recommendations and were subsequently sequenced in duplex. All sequencing was performed at the Weill Medical Centre core genomics facility at Cornell University. ALLPATHS-LG [37] was run using the sequencing libraries described above using default settings. Subsequently, a selection of SMRT-bell sequencing libraries were constructed using various versions of the PacBio RS sequencing kits and chemistries (Additional File 2: Table S2) and PBJelly [17] running default settings was used to incorporate data generated using the PacBio RS platform (Pacific Biosciences) into the ALLPATHS-LG Illumina assembly scaffolds. Identification of benchmarking universal single-copy orthologs (BUSCOs) was performed using BUSCO v3 [18] running default parameters and using 1,440 BUSCO groups.

Gene prediction, annotation, determination of gene orthology and evaluation of synteny between Potentilla and Fragaria genomes

First, ab initio repeat finding was done with RepeatModeler [38] that was run on the complete set of genomic scaffolds set and a repeat library was created. Next, the genome was masked using RepeatMasker [39]. Gene prediction was done with GeneMark-ET [40]. The following parameters were used; a minimum scaffold length of 10 kb, a maximum scaffold gap size of 40 kb, a minimum intron size of 50 bp, a maximum intron length of 10 kb and a maximum intergenic length of 50 kb. RNA-seq reads from the 12 libraries were aligned to the genome sequence scaffolds using the STAR
tool with default parameters [41]. Reads from the 12 RNA-seq datasets were aligned to the genome. Mapping of RNA-seq reads that included intron junctions led to the identification of introns. Introns with a high ‘intron score’ (identified by more than 60 RNAseq reads) were considered to be reliably identified. Predicted genes were annotated using BLAST2GO [42]. The non-redundant NCBI protein database was downloaded and BLAST was run locally. Results from the BLAST analysis were uploaded to the BLAST2GO server and gene ontology analyses were performed using default parameters.

Orthologous relationships between Fragaria and Potentilla genes was determined through sequence clustering performed using Inparanoid 7 [43]. Analyses were based only on homology, as an alternative to the more stringent ortholog classification. Prunus persica v2.0.a1 predicted proteins downloaded from the GDR [44] and Potentilla micrantha and Fragaria vesca protein sequences were blasted all against all and the output file was filtered at the following thresholds: maximum E-value=10^-4 and query coverage of at least 50%. The resulting file was used as an input to the MCL algorithm using as edge weight -log_{10}(evalue) (all E-values=0 were changed to 1E-300). To explore more thoroughly the homology network used as input, the MCL algorithm was run at different granularity levels (inflation parameter equal to 1.5, 1.7, 2.0, 2.3, 2.4, 2.7, 3) and then a table indicating cluster memberships at the different stringencies was compiled for each node. Ortholog classification was produced using Inparanoid 7 [43] for pairs of species in all combinations. The resulting sqltables were then used as an input for QuickParanoid (http://pl.postech.ac.kr/QuickParanoid/) and the sequences were combined in a three-species ortholog classification. The clusters obtained with QuickParanoid were used to calculate the number of genes contained in each cluster for both Potentilla and Fragaria.

Potentilla gene predictions were used as queries to identify the physical locations of orthologous sequences on the F. vesca v2.0 pseudomolecules. Since the Potentilla genomic scaffolds were not oriented and ordered against a reference genetic map, conservation of synteny between the Potentilla and Fragaria genomes was determined through a comparison of the physical positions of orthologous
gene sequences on the sequence scaffolds of *Potentilla* and the pseudomolecules of *Fragaria*. Criteria for the identification of syntenic regions followed that of Jung et al (2012). No attempt was therefore made to infer macro-syntenic structure on a chromosome scale between the two genomes.

**Gene expression during stages of fruit development in *Potentilla micrantha* and *Fragaria vesca***

The quality of the raw reads generated as described above was checked with FastQC [45]; Trimmomatic [46] was used to remove adapter sequences. The *F. vesca* .sra files [8] were used to compare gene expression in *Fragaria* with *Potentilla*; *Fragaria* reads from the same developmental stage were merged and treated as a single data set since data from *Potentilla* was not generated from individual floral organs. The 12 trimmed *P. micrantha* RNA-seq libraries were mapped on the *P. micrantha* gene prediction CDs, while the ten *F. vesca* sets were mapped to the *F. vesca* v1.0 gene prediction CDs [9] downloaded from the GDR [44] using Bowtie2 [47] and default settings. The number of reads mapping to each gene for each RNA set was calculated from the .sam alignment files derived from Bowtie2.

Counts of RNA-seq reads over transcripts were used to calculate the gene expression level in FPKM=10^9*ER/(EL \times MR)*, where *ER* was the number of mapped reads in the exons of a particular gene, *EL* was the sum of exon length in base pairs, and *MR* was the total number of mapped reads [48]. FPKM was used to distinguish expressed genes from inactive genes (those not returning any expression data) during the flower development in each species. Further, FPKM was used to define a set of highly expressed genes: Genes were considered as ‘highly-expressed’ if FPKM>1000. Genes that returned an FPKM<1000 in all samples were removed from further differential expression analysis. The retained differentially expressed genes were processed by performing a linear rescaling of the log2-counts, aligning the distributions for every sample at their distribution modes, followed by variance stabilization to ensure homoscedasticity. A one-way ANOVA was performed gene-by-gene on the rescaled log2-counts to detect changes in expression among different developmental phases. Differentially expressed genes (DEGs) were selected by setting cutoffs both on the p-values...
from the ANOVA F-tests, as well as on the magnitude of observed changes represented by the square 
root of the ANOVA MSR values (equivalent to using volcano plots for two-condition studies). Genes 
were considered differentially expressed if the sqrt (MSR) > 2.00 and p-value < 10\(^{-3}\).

Gene Ontology enrichment analysis of DEGs sets of *Potentilla micrantha* and *Fragaria vesca* was 
carried out using Blast2GO 2.8.0 [49] with “Fisher’s exact test” method, considering as “enriched” 
the GO categories with FDR<0.05. *Potentilla micrantha* whole transcriptome functional annotation 
obtained in this work was used as background for *Potentilla* GO enrichment analysis, while the 
“InterPro GO for GeneMark hybrid transcripts” database downloaded from GDR website was used 
as background for *Fragaria vesca*. Cytoscape 3.5.1 [50] with the BiNGO 3.0.3 plugin was used for 
the GO-slim network visualization of enriched GO categories over *Fragaria vesca* and *Potentilla 
micrantha* DEGs. For determination of over-representation, the Benjamini and Hochberg FDR-
adjusted significance level cutoff was 0.05.

**Phylogenetic and functional analysis of MADs-box domain-containing genes and gene 
expression profile mapping**

Protein sequences of *Potentilla* (this publication) and *Fragaria* (Fvesca_v1.0_hybrid; 
www.rosaceae.org) were analysed on the NCBI conserved domain database [51]. All proteins 
containing a MADs-box domain were retrieved and the MADs-box extracted with Bedtools getfasta 
[52] using default parameters. An initial sequence alignment was carried out using ClustalW and 
pairwise distances were calculated to eliminate outliers. A total of 16 sequences were removed from 
further analysis since they were too short and possessed incomplete N-terminal ends, indicating they 
were likely pseudogenes. The alignment used for phylogenetic analysis was constructed with SATé-
II [53] and contained 156 protein sequences (75 from *Potentilla* and 81 from *Fragaria*).

Three methods, Maximum Likelihood (ML), Maximum Parsimony (MP) and Neighbour-joining 
(NJ), each with 1,000 bootstrap replicates were employed for phylogenetic reconstruction of the
MADS-box domain containing genes using Mega 7.0.14 [54]. Where missing data was present in the alignment, deletion of columns containing a fraction of missing data above 10% and 30% was performed for ML and MP methods. Pairwise deletion was instead used in the case of NJ, to maximise the phylogenetic information retained in the alignment. The ML topology was used as reference for further analysis.

The expression profiles of the genes containing a MADS-box were used to decorate the phylogenetic tree using iTOL v2 [55], allowing the identification of orthologous MADS-box gene pairs displaying differential gene expression profiles between *Potentilla* and *Fragaria*. Curated annotation of differentially expressed putative gene function was carried out using BLASTp homology searches of the TAIR database [56].

**Analysis of the repetitive component of *Potentilla* genome**

To identify and characterize genomic repeats in the *P. micrantha* genome, a reduced set of 2,000,000 randomly selected genomic Illumina reads, corresponding to 0.57× of the *P. micrantha* genome were subjected to clustering using RepeatExplorer [57]. Among the clusters produced, the top clusters, with a genome proportion higher than 0.01%, were annotated using 0.2 as cutoff for cluster connection through mates. Clusters that were annotated as similar to phi-X174 were removed as contaminants. The output of RepeatExplorer was also used to prepare an in-house library containing all contigs belonging to clusters annotated by RepeatExplorer as long terminal repeat retrotransposons (LTR-REs) by similarity search against RepBase [58]. Subsequently, pairwise hybrid clustering between a random set of 1,431,114 Illumina reads derived from *P. micrantha* genomic DNA and 1,090,102 *F. vesca* genomic reads, each corresponding to 0.41× of the respective genomes was performed using RepeatExplorer [57].

**Potentilla full-length LTR-RE characterization**

LTR-FINDER [59] was used to isolate putative full-length LTR-REs from 280 randomly-selected
Potentilla genome sequence scaffolds and alignment boundaries were obtained by adjusting the ends of LTR-pair candidates using the Smith–Waterman algorithm. These boundaries were re-adjusted based on the occurrence of the following typical LTR-RE features: (a) the putative LTR-RE were flanked by the dinucleotides TG and CA at 5′ and 3′ ends respectively; (b) a target-site duplication (TSD) of 4–6 nt in length was present in the sequence; (c) a putative 15–18 nt primer binding site (PBS) complementary to a tRNA at the end of the putative 5′-LTR was present in the sequence; and (d) a 20–25-nt polypurine tract (PPT) just upstream of the 5′ end of the 3′ LTR was present in the sequence. Putative LTR-REs were manually validated using DOTTER [60], verifying the occurrence of LTRs, dinucleotides TG and CA at the 5′ and 3′ ends respectively, and TSDs. The validated LTR-REs were annotated using BLASTX and BLASTN querying the NCBI nr nucleotide and protein NCBI databases and RepBase [58]. To limit false-positive detection, a fixed E-value threshold of E < 10^-5 for BLASTN and E < 10^-10 for BLASTX was used. The full-length elements identified were analysed using RepeatExplorer [57], performing searches for GAG, protease, retrotranscriptase, RNAseH, integrase, and chromodomain derived from plant protein domains from RepBase. The similarity search was filtered at E-value < 10^-10, allowing for both mismatches and frameshifts. The same tool was used to assign full-length elements to specific Gypsy or Copia lineages. Full-length LTR-REs that were identified as belonging to Gypsy or Copia superfamilies, and clusters annotated as LTR-retrotransposons by RepeatExplorer (see above) were then used as reference datasets for further searches in order to identify previously unclassified elements using RepeatMasker, running default parameters, but with -div set to 20.

For determination of RE redundancy, approximately 32,000,000 randomly-selected raw Potentilla Illumina paired end reads, corresponding to 10.3× genome coverage. After removal of organellar contamination performed by mapping the reads to an in-house Rosaceae organellar database and the removal of duplicate reads, a total of 25,206,510 filtered nuclear reads corresponding to 7.2× equivalent genomic coverage were used for redundancy analysis by mapping the reads to all REs characterized in the Potentilla genome using CLC-BIO Genomic Workbench 8.0 (CLC-BIO, Aarhus,
Mismatch cost, deletion cost, and insertion cost were fixed at 1, and similarity and length fraction were both fixed at 0.9, 0.8, 0.5 or 0.4 to obtain high, medium, low, or very low stringencies, respectively. As reads that mapped to multiple distinct sequences were few, and distributed randomly throughout the dataset, the number of reads mapping to each RE was taken as the degree of redundancy of that sequence within the genome. The effective abundance of a particular class of reads was calculated as the proportion of the total number of reads mapped in each class, with respect to the overall number of genomic reads mapped, using optimal stringency parameters, i.e. where further relaxation of stringency did not significantly increase the number of mapped reads.

The abundance of each single RE sequence in the genome was analysed by mapping Potentilla DNA reads, corresponding to 2× genome coverage to the full-length REs characterised, one by one using BWA (alignment via Burrows–Wheeler transformation) version 0.7.5a-r405 [61] running the following parameters: bwaaln -t 4 -l 12 -n 4 -k 2 -o 3 -e 3 -M 2 -O 6 -E 3. The resulting single-end mappings were resolved via the samse module of BWA, and the output was converted to .bam file format using SAMtools version 0.1.19 [62]. Subsequently, SAMtools was used to calculate the number of mapped reads for each alignment using the following parameters: samtools view -c -F 4.

**Determination of RE insertion age**

Retrotransposon insertion age was estimated through a sequence divergence comparison of the 5′- and 3′-LTRs of each putative full-length retrotransposon. Synonymous substitution rates were calculated for 50 pairs of orthologous gene sequences of *P. micrantha* and *F. vesca*, using a time of divergence of 24.22 million years [3]. Subsequently, the two LTRs were aligned with ClustalX software [61], indels were eliminated, and the number of nucleotide substitutions was counted using DnaSP [62] for each retrotransposon. The insertion times of retrotransposons with both LTRs were dated using the Kimura two parameter (K2P) method [65], calculated using DnaSP, and a synonymous substitution rate that is twofold that calculated for genes [66,67].
AVAILABILITY OF SUPPORTING DATA AND MATERIALS

The data set supporting the results of this article are available in the GenBank repository, project number PRJEB18433. The genome reference sequence and gene predictions can be downloaded from the GigaScience GigaDB repository.

FUNDING

This work was funded by a grant to the Fondazione Edmund Mach (FEM) from the Autonomous Province of Trento grants office. A.C. acknowledges funding from the Department of Agriculture, Food and Environment of Pisa University, Project ‘Plantomics’.

CONFLICT OF INTERESTS

The authors declare no competing interests.

AUTHOR CONTRIBUTIONS

M.Buti performed the experiments, analysed and interpreted all data and authored the paper. M.M., P.S. and A.C. analysed sequence data and performed genome assemblies. K.E. and M. Brilli assisted with experimental design, analysed and interpreted gene expression data and commented on and contributed to the manuscript. L.N. and A.C. performed full-length retrotransposon isolation. E.B., F.M. and A.C. performed clustering, annotation and redundancy analyses of repetitive sequences. E.B., F.M., L.N. and A.C. participated in the interpretation and discussion of results and contributed to the writing of the paper. A.L and M.Borodovsky performed gene predictions and analysed and interpreted the data. L.G., N.Š. assisted with experiments, interpreted data and contributed to the manuscript. M.A. and J.W. assisted with genome assemblies and gene annotation. C.V. analysed and interpreted phylogenetic data and contributed to the manuscript. R.V. commented on the manuscript.
D.J.S. designed the study, assisted with the experiments, analysed and interpreted the data and authored the paper.

Figure 4: Scatter plots showing distribution of p-values against sqrt(MSE) for two species, Potentilla micrantha and Fragaria vesca. The plots display data for 1556 and 816 genes, respectively.

Dear Editor,

Please find attached the revision of our original article. Below please find a point-by-point description of the changes made in the light of the reviewers’ comments. We would like to thank both you and the reviewers, as we feel the changes that have been made have significantly enhanced and strengthened the paper.

**Reviewer 1**

We have toned down the whole of the manuscript to reflect the descriptive nature of our data and have likewise changed the title of the paper to: The genome sequence and transcriptome of *Potentilla micrantha* and their comparison to *Fragaria vesca* (the woodland strawberry).

The figure legends have been checked and corrected where necessary.

The figure relating to anchoring of scaffolds has been moved to the supplementary material and replaced with figures relating to synteny of specific scaffolds rather than the genome as a whole. Additionally, we have ensured throughout the text that it is clear that only micro-synteny was evaluated.

A BUSCO analysis has been performed and presented.

An analysis showing the overlap between the DEGs in each species was performed, as well as a visualisation of the genes from each species and the GO class they fall into.

The Transposon analysis section has been reduced.

The hormonal treatment analysis has been removed from the paper.

The miR1511 data has been removed from the paper as further work would have been required to strengthen this section sufficiently for publication which was not possible since almost all authors now no longer work at FEM where this work was initiated.

**Reviewer 2**
We appreciate the comments regarding the mechanisms of differentiation, and indeed at the inception of the project this was to be a major focus of the work; however, we were not able to progress in this area sufficiently to make this a major part of the manuscript. We hope that other groups will be able to study this area, building on the work we present here.

We have added a space between x and ananassa.

We have removed the redundancy and made clearer the objectives of the study.

Figure numbering has been corrected.

The ML study is presented the others have been referred to as data not shown.

Plants were selected from Serbia as we had a collaborator there who guided us to a large population from which we could sample plant material easily.

Redundancy has been removed from the HiSeq2000 methods section.

We have adjusted the text relating to FPKM to clarify that highly expressed genes were those with FPKM >1000 and on/off genes were those where no expression data were observed.

A space was added to sqrt (MSR).

Abbreviations have been added for ML, MP and NJ in the text.

Resolution of the figures has been improved and font size increased to improve clarity.

Figure legends for the phylogenetic analysis have been improved. The text resolution on the submitted figures is much better than in the reviewer copy. We hope that in the revised version, the reviewers have access to higher resolution images where text is hopefully clear and legible.

**Reviewer 3**

The text has been modified throughout to make clearer that only micro-synteny was evaluated. Likewise, the figures relating to this section have been changed to reflect and emphasise the micro-synteny.

The abundance of GO terms for the DEGs in each species has been highlighted through an additional figure, and those classes that were in greater abundance are identified. Likewise, a heatmap of the expression levels of genes shared between the two species has been produced and those that differ in their expression patterns have been identified.

The title and text have been toned down to reflect the results presented more accurately.

We look forward to hearing from you in due course regarding this resubmission,

Best regards,
Dan Sargent (on behalf of all authors).
