Background. Age prevalence curves for areas in which schistosomiasis is endemic suggest that humans develop partial immunity to reinfection beginning in early adolescence. We conducted a 2-year longitudinal study to determine whether children infected with Schistosoma mansoni develop protection-related immune responses after treatment with praziquantel and whether the development of these immune responses is accelerated by frequent treatment after reinfection.

Methods. Children (8–10 years old) were tested for S. mansoni every 4 months and treated with praziquantel when positive (arm A; n = 68) or were tested and treated at the end of the 2-year follow-up period (arm B; n = 49).

Results. Children in arm A who remained free of infection during follow-up had significantly higher baseline levels of schistosome-specific immunoglobulin E (IgE) than did children with ≥2 repeat diagnoses of S. mansoni infection. Children with ≥2 repeat diagnoses of S. mansoni infection had significantly increased levels of anti-schistosome IgE and CD23+ B cells after receiving ≥3 praziquantel treatments over the course of follow-up. No increase in either parameter was seen in children who received only the baseline praziquantel treatment.

Conclusions. B cell activation and anti-schistosome IgE are associated with resistance to S. mansoni in children, and these immunological parameters can be increased by multiple rounds of infections and praziquantel-induced cures.

Schistosoma mansoni age prevalence curves for areas of endemicity suggest that intensity and prevalence of infection peak during the early teenage years. Prevalence then plateaus while infection intensity sharply declines as individuals enter the third decade of life. Immunologic studies suggest that the decline in intensity is in part attributable to the development of immunity to new infections [1–3]. Given that the life span of S. mansoni worms is ~5–10 years [4, 5], this resistance to reinfection coincides with the time when worms from the initial infection begin to die. These findings have lead to the hypothesis that worm death, rather than worm maintenance, is responsible for inducing resistance to reinfection [6]. We have previously shown that male adults occupationally exposed to S. mansoni developed increased resistance to reinfection after...
repeated cycles of treatment, reinfection, and retreatment [7].

The most consistent immune parameter associated with resistance to reinfection is increased levels of schistosome-specific immunoglobulin E (IgE) [8–11]. B lymphocytes are the producers of all immunoglobulins, including IgE, and we recently reported an association between the CD23+ B cell subset and increased resistance to reinfection in our cohort of male adults [12]. CD23 is the low-affinity IgE receptor (FceRII), and its expression on B cells is in part considered an indication of their maturity [13]. CD23 binds to a variety of membrane and soluble molecules—such as CD21, CD11b, CD11c, and IgE—and in its soluble form can act as a B cell proliferation factor [14]. The functional roles of the a and b isoforms of membrane-bound and soluble CD23 include B cell development, IgE binding, cell adhesion, antigen presentation to T cells, and regulation of IgE synthesis [15–19].

It has been postulated that resistance to reinfection can develop sooner than early adolescence in areas where endemcity is high or where there are programs leading to the early treatment of infections in children [20–22]. World Health Assembly resolution 54.19 recommends periodic mass treatment of children with the drug praziquantel in areas where schistosomiasis is endemic. Although intended to control morbidity, the periodic killing of adult worms might have the additional benefit of hastening the development of resistance to reinfection by inducing premature worm death. However, the appropriate interval at which treatment should be given to control morbidity or enhance resistance to reinfection has not been extensively evaluated in different epidemiologic settings. The purpose of the present study was to determine whether 8–10-year-old children infected with S. mansoni develop protective immune responses after treatment with praziquantel and whether the development of these anti-schistosome immune responses is accelerated by more frequent treatment over a 2-year period.

METHODS

Study Population

All subjects began the study as 8–10-year-old children recruited from 8 primary schools located within 3 km of Lake Victoria in the Asembo Bay area of the Nyanza Province in western Kenya. S. mansoni is highly endemic in the area. A 2001 survey of schools in the area found that the prevalence of S. mansoni ranged from 35%–80% [23].

After an initial screening of 485 children, 155 of the 179 children who were positive for S. mansoni were enrolled in a 2-year longitudinal study. Children were assigned into treatment arm A (n = 88) or treatment arm B (n = 67). Assignments were made by school except in the case of one school, which had the largest number of students and the highest S. mansoni prevalence. Students in this school were randomized to arm A or B. The final study population consisted of 68 children from arm A (77.3%) and 49 children from arm B (73.1%) who completed the 2 years of follow-up.

Study Procedures

In the baseline survey, all consenting children aged 8–10 years attending the study schools were tested for the presence of S. mansoni eggs by the Kato-Katz method, using 2 slides from a single stool sample. Children positive for S. mansoni were then asked to enroll in a 2-year longitudinal study and assigned to arm A or B as described above. At baseline and each follow-up visit, children provided a stool sample for testing for S. mansoni eggs as well as Ascaris lumbricoides, hookworm, and Trichuris trichiura by the Kato-Katz method, again using 2 slides from a single stool sample. Blood samples were also obtained from children by venipuncture for immunological analysis as well as testing for malaria parasitemia via Giemsa-stained blood smears. Children infected with S. mansoni, soil-transmitted helminths (STHs), or Plasmodium falciparum were treated with praziquantel (40 mg/kg), albendazole (400 mg), or artesunate-lumefantrine (Coartem [Novartis]; 6 doses administered over 3 days), respectively.

Children in arm A were tested and treated every 4 months, for a total of 6 follow-up visits after baseline testing. Children in arm B were tested and treated only at baseline and again at the end of the 2-year follow-up period.

At study entry, a short questionnaire was administered to students in both study arms in which they were asked to characterize how often they went to the lake to engage in such activities as bathing, swimming, or fishing as one of the following: almost every day, sometimes (once a week), rarely (once a month), or never. A similar questionnaire was administered to the parents regarding the water contact behavior of their child. All questionnaires were verbally administered in the local language.

Written informed consent was obtained from the parent or guardian of each child before enrollment, and the children gave verbal assent for participation in the study. Study procedures were approved by the institutional review boards of the University of Georgia and the Centers for Disease Control and Prevention, the Scientific Steering Committee of the Kenya Medical Research Institute (KEMRI), and the KEMRI/National Ethics Review Committee of Kenya.

Immunological Testing

Antibody evaluation. A standardized enzyme-linked immuno- nosorbent assay for soluble worm antigen preparation (SWAP)—specific IgE was performed on plasma from venous blood, as described elsewhere [24]. An external positive control (PC) comprised of a pooled sample of plasma from high-responding adults and a negative control of normal human serum (NHS) from volunteers from areas of nonendemicity was run on each
The prevalence of infection over time. The prevalence of S. mansoni infection at each follow-up time point in arm A is shown in Figure 1. Prevalence was reduced to 34% four months after the initial praziquantel treatment. However, children became rapidly reinfected in this area of endemicity. Even with infected children receiving diagnoses and treatment at 4-month intervals, the prevalence of S. mansoni never decreased to <23% during the 2 years of follow-up.

Thirty-eight children (56%) in arm A had 2 or more positive diagnoses of S. mansoni infection after treatment for the S. mansoni infection present at baseline and before the end of the 2 years of follow-up. Nineteen children (28%) had 1 repeat diagnosis of S. mansoni infection during the course of follow-up, and 11 children (16%) went at least 2 years without becoming reinfected with S. mansoni, although 2 of these children were infected at the 2-year follow-up time point.

Geometric mean baseline egg counts in children with 0, 1, and ≥2 repeat diagnoses of S. mansoni infection were 54 (95% confidence interval [CI], 18–159), 64 (95% CI, 32–127), and 135 (95% CI, 87–209) eggs per gram of feces (epg), respectively. Although there was a trend toward higher initial intensity of infection in children with a greater number of repeat diagnoses of S. mansoni infection, the difference between the groups only approached statistical significance (P = .059). There were no differences in self-reported or parent-reported water contact between these groups.

Forty-three percent of the children in arm B were infected with S. mansoni at the 2-year follow-up time point, which approximated the overall baseline prevalence of 37% found in the initial survey of these schools. The mean intensity of infection among stool-positive children at the 2-year follow-up time point was 99 (standard deviation, 172) epg in arm A and 172 (standard deviation, 219) epg in arm B; the difference between arms was not significant (P = .298).

Changes in anti-SWAP IgE levels. Standardized anti-SWAP IgE levels at baseline and the 2-year follow-up time point in arms A and B are shown in Figure 2. Although anti-SWAP IgE levels slightly increased over the 2-year period, there were no statistically significant differences between baseline and 2-

### RESULTS

#### Baseline demographics

Baseline demographic characteristics of the study population are shown in Table 1. There were no significant differences between the 2 study arms in intensity of S. mansoni infection, sex, or coinfection with *P. falciparum* or STHs. Both groups had a similarly high frequency of self-reported water contact, with ~95% of children reporting contact with the lake at least once a month and >85% reporting weekly contact with the lake. In addition, there were no significant differences in any of these demographic factors between those children who did and those who did not complete the entire 2 years of follow-up.

S. mansoni infection over time. The prevalence of S. mansoni infection at each follow-up time point in arm A is shown in Figure 1. Prevalence was reduced to 34% four months after

a. Contact with lake at least once a month.

b. Contact with lake at least once a week.

#### Statistical Analyses

The Wilcoxon rank sum test or the Kruskal-Wallis test was used for 2-sample or multiple-sample group comparisons, respectively. The Wilcoxon signed rank test was used for paired comparisons of the same children at different time points. All analyses were performed with Prism software (version 5; GraphPad) or SAS software (version 9.1; SAS Institute).

#### Figures

Figure 1. Prevalence of *Schistosoma mansoni* infection at each follow-up time point in study arm A.
year follow-up anti-SWAP IgE levels in either arm. There were also no statistically significant differences in baseline anti-SWAP IgE levels between arms A and B or in final anti-SWAP IgE levels between arms A and B.

Figure 3 depicts standardized anti-SWAP IgE levels at baseline and final follow-up for children in arm A, stratified by the number of repeat diagnoses of *S. mansoni* infection made during the 2 years of follow-up. Baseline anti-SWAP IgE levels in children with ≥2 repeat diagnoses were significantly lower than baseline levels in children who went at least 2 years without becoming reinfected. There was also a significant trend in decreasing baseline anti-SWAP IgE levels among children with 0, 1, and ≥2 repeat diagnoses of *S. mansoni* infection (*P* = .002). Children who had ≥2 repeat diagnoses (and who thus received a total of 3 or more treatments with praziquantel) over the 2 years of follow-up demonstrated significant increases in anti-SWAP IgE levels between baseline and the final 2-year follow-up time point. There were no significant changes in anti-SWAP IgE levels over time in those children who were not given a repeat diagnosis (and who thus received only the initial praziquantel treatment at baseline) or in those children who were given 1 repeat diagnosis (and who thus received a total of 2 praziquantel treatments) (Figure 3).

**Changes in CD23+ B cell percentages.** The mean percentage of CD23+ B cells in children in both study arms at baseline and the final follow-up time point is shown in Figure 4. The percentage of CD23+ B cells significantly increased between baseline and the 2-year follow-up time point in both arm A and arm B, but the difference in the CD23+ B cell percentage between the 2 arms at the 2-year follow-up time point was not statistically significant (*P* = .076).

When arm A was stratified by the number of repeat diagnoses of *S. mansoni* infection during follow-up (Figure 5), changes in CD23+ B cell percentages showed a pattern similar to that seen with anti-SWAP IgE levels. Although the difference did not reach statistical significance (*P* = .098), children who were not reinfected before the 2-year follow-up time point had a higher percentage of CD23+ B cells at baseline than did children who had ≥2 repeat diagnoses of *S. mansoni* infection over the course of follow-up. The percentage of CD23+ B cells increased between baseline and the 2-year follow-up time point in children who had ≥2 repeat diagnoses of *S. mansoni* infection over the course of follow-up (and who thus received ≥3 praziquantel treatments) as well as in those children who had 1 repeat diagnosis (and who thus received 2 praziquantel treatments). However, the percentage of CD23+ B cells did not change significantly in those children who were not reinfected before the final follow-up (and who thus received only the initial praziquantel treatment).

**Coinfection with *P. falciparum* and STHs.** There was no difference in baseline anti-SWAP IgE levels between children coinfected with *S. mansoni* and *P. falciparum* and children without *P. falciparum* infection (standardized OD value, 0.058 vs 0.055; *P* = .282) or between children coinfected with *S. mansoni* and STHs and children without STH infection (standardized OD value, 0.062 vs 0.046; *P* = .943). There was also no difference in CD23+ B cell percentage between children coinfected with *S. mansoni* and *P. falciparum* and children without *P. falciparum* infection (49.3% vs 46.9%; *P* = .533). There was a higher percentage of CD23+ B cells in children coinfected with *S. mansoni* and STHs than in children without STH infection (57.8% vs 41.5%; *P* = 0.018). However, the difference in CD23+ B cell percentage in children infected with STHs and those not infected with STHs did not persist at the first follow-up time point (4 months) after treatment with albendazole and/or praziquantel (50.8% in STH-infected children and 51.6% in

STH-uninfected children). This was true regardless of S. mansoni infection status at 4 months (data not shown). At no other time point throughout the course of follow-up did children infected with STHs have a higher percentage of CD23+ B cells than children not infected with STHs.

**DISCUSSION**

Our data suggest high S. mansoni transmission in this area along Lake Victoria in western Kenya. After 2 years of diagnosing and treating infected children every 4 months, the prevalence of S. mansoni in arm A of our cohort was still ∼30%. This is close to the overall prevalence of 37% found in our initial survey of 8–10-year-old children in the study area. More than half (56%) of the children in arm A had 2 or more positive diagnoses of S. mansoni infection during the 2 years after treatment of the initial infection. Because we did not assess cure after each treatment, we cannot be certain that each positive diagnosis represented a reinfection rather than a cure failure. However, given that the cure rate of praziquantel is 170% after 1 dose [25, 26], the majority of these positive diagnoses likely represented true cures and reinfections.

The original design of the study was to examine differences in immune parameters between children kept as free of S. mansoni infection as possible for 2 years (arm A) and children treated only once 2 years prior (arm B). When arm A was analyzed as a group, however, we did not find a difference in levels of schistosome-specific IgE between arms A and B at the end of the study. What we did not anticipate was that some children in this area had developed an apparent level of resistance to S. mansoni before age 8–10 years (when they were enrolled in this study), as they did not become reinfected for 2 years after 1 praziquantel treatment. When arm A was stratified according to the number of diagnoses of S. mansoni infection, each child had during follow-up, which is a close approximation of how many times the child was reinfected, those children who did not become reinfected for at least 2 years after treatment of their baseline infection had significantly higher levels of anti-SWAP IgE and borderly significantly higher levels of CD23+ B cells than did the more susceptible children who had at least 2 repeat diagnoses of S. mansoni infection (and likely >2 reinfections) within 2 years. After 3 or more praziquantel treatments, both anti-SWAP IgE and the percentage of CD23+ B cells had significantly increased in the more susceptible children, indicating that frequent treatment of infected children can drive immune responses to more closely resemble those of the children who remained uninfected over the course of follow-up.

Numerous studies have reported an association between higher levels of schistosome-specific IgE and resistance to reinfection with S. mansoni [8–11]. We recently reported increases in anti-SWAP IgE levels that paralleled the change from a state of susceptibility to S. mansoni infection to a state of increased resistance to reinfection in our cohort of male adults undergoing repeated cycles of treatment and reinfection [27]. We also recently reported a correlation between CD23+ B cell percentage and level of resistance to S. mansoni reinfection in our cohort of male adults, suggesting that B cells expressing CD23 may play a role in the development of protective immunity [12]. CD23 is the low-affinity receptor for IgE and has been shown to be essential for IgE-mediated enhancement of specific immune responses in murine models [28].

We did not observe an increase in anti-SWAP IgE levels in children who received 2 praziquantel treatments over the course of follow-up. However, this group was likely composed of children who experienced cure failure after the initial praziquantel treatment, children who had already developed an intermediate level of resistance, and children who had >1 reinfection but whose reinfections were not diagnosed as repeat positive results because of the insensitivity of the Kato-Katz test on a single stool sample. Although there was an overall increase in the percentage of CD23+ B cells during the 2-year period in both

![Figure 4](image-url) Percentage of CD19+CD23+ cells at baseline and the 2-year follow-up time point in study arms A and B. SEM, standard error of the mean.

![Figure 5](image-url) Percentage of CD19+CD23+ cells at baseline and the 2-year follow-up time point in study arm A, stratified by the number of praziquantel treatments received during the 2-year follow-up period. SEM, standard error of the mean.
study arms, this was not unexpected given that studies have shown that the proportion of B lymphocytes expressing CD23 slowly increase until age 12 in healthy pediatric populations [29, 30]. However, within arm A the increase was more dramatic among the more susceptible children who received ≥3 praziquantel treatments than among the more resistant children who required only 1 initial praziquantel treatment.

A high level of coinfection with \textit{S. mansoni}, \textit{P. falciparum}, and STHs was present in this population. We found no association between levels of schistosome-specific IgE and coinfection with either \textit{P. falciparum} or STHs. Children coinfected with STHs and \textit{S. mansoni} at baseline had a statistically significantly higher percentage of CD23+ B cells than did children without STH infection. A higher percentage of CD23+ B cells in coinfected children was seen only at baseline, when they likely had long-term \textit{S. mansoni} and STH infections. The difference did not persist after treatment of their infections at baseline.

In conclusion, we found that some children in this area of high endemicity exhibited a phenotype indicative of resistance to \textit{S. mansoni} reinfection by 8–10 years of age. Infections in lakeside communities have been shown to begin very early in life [31], and some of our 8–10-year-old subjects could have been infected for 7–9 years at the time of their enrollment, providing an opportunity for them to have already experienced dying worms. The resistant phenotype was characterized by high schistosome-specific IgE levels and elevated levels of CD23+ B cells. Frequent praziquantel treatment of more susceptible children increased these immune responses toward protective levels. The effect of praziquantel treatment on the production of anti-SWAP IgE and CD23+ B cells was obscured when data were analyzed without accounting for differences in prior development of apparent resistance to \textit{S. mansoni}.
