It is widely recognized that the risk of secondary neoplasms increases as childhood cancer survivors progress through adulthood. These are mainly hematological malignancies, and recurrent chromosome translocations are commonly detected in such cases. On the other hand, while secondary epithelial malignancies have sometimes been reported, chromosome translocations in these epithelial malignancies have not. A 33-year-old man who had been diagnosed with acute lymphoblastic leukemia and treated with chemotherapy almost 20 years earlier was diagnosed with lung adenocarcinoma. After chromosomal rearrangement of echinoderm microtubule-associated protein-like 4 gene and the anaplastic lymphoma kinase gene was detected in this adenocarcinoma, he responded to treatment with crizotinib. It was therefore concluded that this echinoderm microtubule-associated protein-like 4 gene–anaplastic lymphoma kinase gene-positive lung adenocarcinoma was a secondary epithelial malignancy.

Key words: cancer survivor – EML4–ALK – secondary lung adenocarcinoma

INTRODUCTION

The survival rate of patients with childhood cancer has increased from 1970 to the present, with 5-year survival rates now approaching 80% (1). Coincident with this improved survival has been the recognition that survivors are at risk for subsequent malignancies (2–6). It has been widely accepted that the anti-cancer drugs used in childhood damage the genomic DNA of some hematopoietic progenitors, resulting in secondary hematological malignancies (7). Indeed, recurrent chromosome translocations were found in many cases of such malignancies (7, 8). On the other hand, no chromosomal translocations have been reported in secondary epithelial malignancies.

Chromosomal rearrangement of the echinoderm microtubule-associated protein-like 4 gene (EML4) and of the anaplastic lymphoma kinase gene (ALK) leads to an oncogenic fusion gene that was first reported in lung adenocarcinoma (9). This translocation may occur in <5% of non-small cell lung cancers (NSCLCs) and has come to be recognized as a new target of chemotherapy (9). To the best of our knowledge, this is the first report of a case of an EML4–ALK-positive lung adenocarcinoma that occurred almost 20 years after treatment for acute lymphoblastic leukemia (ALL).

CASE REPORT

A 33-year-old man who had never smoked was referred to our institution for further examination of a massive right pleural effusion on chest X-ray. Thoracentesis was performed, and pleural fluid cytology was positive for adenocarcinoma. A computed tomography (CT) scan of his chest after the thoracentesis revealed a nodule in the right upper lobe ~3 cm in diameter (Fig. 1), and Stage IV NSCLC was diagnosed. When the patient was 11 years old, he had been diagnosed...
with ALL and enrolled in a clinical trial for juvenile high-risk ALL (10). He had been treated with the AL851 regimen, receiving vincristine, prednisolone, daunorubicin, l-asparaginase, methotrexate, 6-mercaptopurine, doxorubicin, cytosine arabinoside, 6-mercaptopurine, and cyclophosphamide. Cranial irradiation was used to prevent central nervous system leukemia; however, thoracic irradiation was not performed (10). Complete remission was achieved.

Considering his medical history, he was found to have a secondary lung adenocarcinoma at an advanced stage. Mutation analysis of mononuclear cells in his pleural fluid indicated that his tumor carried the wild-type epidermal growth factor receptor gene (EGFR). After pleurodesis, treatment with carboplatin and paclitaxel with bevacizumab was started. During this first-line treatment, it was suspected that his lung adenocarcinoma could be an EML4–ALK-positive tumor, given the fact that he was young and his tumor was negative for EGFR mutations. Thus, the multiplex reverse-transcription polymerase chain reaction (RT-PCR) was performed to test for EML4–ALK fusion complementary DNA (cDNA) in his tumor cells (Forward primer; 5'-GTGCAGTGTTAGCATTCTTGGGG-3' and reverse primer; 5'-TCTTGCCAGCAAAACGAGTAGTGGG-3') (11). As shown in Fig. 2, RT-PCR showed that his tumor did indeed carry EML4–ALK. Nucleotide sequencing of this PCR product further confirmed the presence of EML4–ALK variant 1 cDNA in which exon 13 of EML4 was fused in-frame to exon 20 of ALK (Fig. 3). These data suggest that the patient had a secondary EML4–ALK-positive NSCLC.

After four cycles of carboplatin and paclitaxel with bevacizumab and two cycles of bevacizumab maintenance treatment, his tumor progressed. He was then treated with crizotinib, an ALK-specific inhibitor. The tumor initially responded to crizotinib, but became refractory after several months of treatment. After that, several chemotherapy regimens, including pemetrexed, cisplatin plus docetaxel, gemcitabine and TS-1, were administered; however, all were ineffective. He died almost 2 years after the diagnosis of lung cancer.

DISCUSSION

This patient had been diagnosed with and treated for ALL almost 20 years earlier and subsequently diagnosed with lung adenocarcinoma. It is widely recognized that the risk of secondary malignancies increases as childhood-cancer survivors progress through adulthood (1–6). There is no widely accepted definition of secondary malignant neoplasm; however, considering the definition of the Childhood Cancer Survivor Study (CCSS) (1), we concluded that his lung adenocarcinoma was a secondary malignant neoplasm. In the CCSS report, the most frequent secondary epithelial malignancies occurring ≥5 years after childhood cancer were breast and thyroid cancer. However, bronchial and lung cancers were also epithelial malignancies whose subsequent risks were elevated. The 30-year cumulative incidence for selected subsequent cancers was 0.1% for lung cancer, and the standardized incidence ratio (SIR) of second bronchial and lung cancers was 3.4 (95% confidence interval [CI] = 1.9–6.1) (1).
Recurrent chromosome translocations were found in most cases of secondary hematological malignancies after childhood ALL treated with Berlin-Frankfurt-Munster (BFM)-based regimens (8). Several anti-cancer drugs are considered to be potent clastogenic agents. Thus, secondary hematological malignancies may result from illegitimate recombination of chromosomal fragments caused by such anti-cancer agents (7). In this regard, BFM-based treatment might play a direct role in chromosome translocations detected in secondary malignancies. On the other hand, oncogenic driver mutations, such as EGFR mutant or K-ras mutant, have not been reported in relation to secondary lung cancer so far. This case also did not harbor any EGFR mutations. In this regard, oncogenic point mutations in lung cancer may have only a weak association with carcinogenicity of anti-cancer drugs.

It was previously accepted that recurrent chromosome translocations play a major role in the molecular pathogenesis of hematological malignancies, but not solid tumors. However, the discovery of EML4–ALK generated through inv (2) (p21p23) has changed this notion (9). This fusion gene encodes an oncogenic EML4–ALK fusion-type tyrosine kinase. Wild-type ALK is thought to undergo transient homodimerization in response to binding to its specific ligands, resulting in its activation. On the other hand, EML4–ALK is constitutively oligomerized via the coiled-coil domain within EML4, leading to persistent mitogenic signals that eventually lead to malignant transformation (9).

Brenner and Hall (12) described the risk of second malignancies associated with CT. Indeed, Mathews et al. (13) identified CT scans as a risk factor for second malignancies in a large cohort trial. However, the risk of lung cancer was not increased in their report, and the present patient received only one or two CT scans during his leukemia treatment and never underwent CT prior to that. Thus, we consider that the effect of irradiation was very limited in this secondary lung adenocarcinoma.

The occurrence of secondary EML4–ALK-positive lung cancer in the present case could have been the result of the patient’s initial treatment for childhood ALL. Considering this case, known or unknown oncogenic recurrent chromosome translocations or DNA rearrangement might be present in other secondary epithelial malignancies, which should be carefully investigated by physicians who treat patients with all types of secondary malignancies.
